Index .............................................................................. 652
This book has been written assuming that the reader executes all the commands presented in the text and follows all the instructions at the same time. If this advice is neglected, then the book will be of little help and some parts of the text may seem incomprehensible.

The book’s website is at
http://www.physics.ntua.gr/~konstant/ComputationalPhysics/
From there, you can can download the accompanying software, which contains, among other things, all the programs presented in the book.

Some conventions: Text using the font shown below refers to commands given using a shell (the “command line”), input and output of programs, code written in Fortran (or any other programming language), as well as to names of files and programs:

```
> echo Hello world
Hello world
```

When a line starts with the prompt

```
>
```

then the text that follows is a command, which can be given from the command line of a terminal. The second line, Hello World, is the output of the command.

The contents of a file with Fortran code is listed below:

```
program add
  z = 1.0
  y = 2.0
  x = z + y
  print *, x
end program add
```

What you need in order to work on your PC:
• An operating system of the GNU/Linux family and its basic tools.

• A Fortran compiler. The gfortran compiler is freely available for all major operating systems under an open source license at http://www.gfortran.org.

• An advanced text editor, suitable for editing code in several programming languages, like Emacs.

• A good plotting program, suitable for data analysis, like gnuplot.

• The shell tcsh.

• The programs awk, grep, sort, cat, head, tail, less. Make sure that they are available in your computer environment.

If you have installed a GNU/Linux distribution on your computer, all of the above can be installed easily. For example, in a Debian like distribution (Ubuntu, ...) the commands

```
> sudo apt-get install tcsh emacs gnuplot-x11 gnuplot-doc
> sudo apt-get install gfortran gawk gawk-doc binutils
> sudo apt-get install manpages-dev coreutils liblapack3
```

install all the necessary tools.

If you don’t wish to install GNU/Linux on your computer, you can try the following:

• Boot your computer using a usb/DVD live GNU/Linux, like Ubuntu. This will not make any permanent changes in your hard drive but it will start and run slower. On the other hand, you may save all your computing environment and documents and use it on any computer you like.

• Install Cygwin in your Microsoft Windows. It is a very good solution for Microsoft-addicted users. If you choose the full installation, then you will find all the tools needed in this book.

² http://www.gnu.org/software/emacs/
³ http://www.gnuplot.info
⁴ http://www.tcsh.org
⁵ http://www.gnu.org/software/gawk
⁶ http://www.ubuntu.com
⁷ http://www.cygwin.com
• Mac OS X is based on Unix. It is possible to install all the software needed in this book and follow the material as presented. Search the internet for instructions, e.g. google “gfortran for Mac”, “emacs for Mac”, “tcsh for Mac”, etc.
Foreword

This book is the culmination of my ten years’ experience in teaching three introductory, \textit{undergraduate level}, scientific computing/computational physics classes at the National Technical University of Athens. It is suitable mostly for junior or senior level science courses, but I am currently teaching its first chapters to sophomores without a problem. A two semester course can easily cover all the material in the book, including lab sessions for practicing.

Why another book in computational physics? Well, when I started teaching those classes there was no bibliography available in Greek, so I was compelled to write lecture notes for my students. Soon, I realized that my students, majoring in physics or applied mathematics, were having a hard time with the technical details of programming and computing, rather than with the physics concepts. I had to take them slowly by the hand through the “howto” of computing, something that is reflected in the philosophy of this book. Hoping that this could be useful to a wider audience, I decided to translate these notes in English and put them in an order and structure that would turn them into “a book”.

I also decided to make the book freely available on the web. I was partly motivated by my anger caused by the increase of academic (e)book prices to ridiculous levels during times of plummeting publishing costs. Publishers play a diminishing role in academic publishing. They get an almost ready-made manuscript in electronic form by the author. They need to take no serious investment risk on an edition, thanks to print-on-demand capabilities. They have virtually zero cost ebook publishing. Moreover, online bookstores have decreased costs quite a lot. Academic books need no advertisement budget, their success is due to their academic reputation. I don’t see all of these reflected on reduced book prices, quite the contrary, I’m afraid.

My main motivation, however, is the freedom that independent publishing would give me in improving, expanding and changing the book in the future. It is great to have no length restrictions for the presenta-
tion of the material, as well as not having to report to a publisher. The reader/instructor that finds the book long, can read/print the portion of the book that she finds useful for her.

This is not a reference book. It uses some interesting, I hope, physics problems in order to introduce the student to the fundamentals of solving a scientific problem numerically. At the same time, it keeps an eye in the direction of advanced and high performance scientific computing. The reader should follow the instructions given in each chapter, since the book teaches by example. Several skills are taught through the solution of a particular problem. My lectures take place in a (large) computer lab, where the students are simultaneously doing what I am doing (and more). The program that I am editing and the commands that I am executing are shown on a large screen, displaying my computer monitor and actions live. The book provides no systematic teaching of a programming language or a particular tool. A very basic introduction is given in the first chapter and then the reader learns whatever is necessary for the solution of her problem. There is more than one way to do it and the problems can be solved by following a basic or a fancy way, depending on the student’s computational literacy. The book provides the necessary tools for both. A bibliography is provided at the end of the book, so that the missing pieces of a puzzle can be sought in the literature.

This is also not a computational physics playground. Of course I hope that the reader will have fun doing what is in the book, but my goal is to provide an experience that will set the solid foundation for her becoming a high performance computing, number crunching, heavy duty data analysis expert in the future. This is why the programming language of the core numerical algorithms has been chosen to be Fortran, a highly optimized, scientifically oriented, programming language. The computer environment is set in a Unix family operating system, enriched by all the powerful GNU tools provided by the FSF. These tools are indispensable in the complicated data manipulation needed in scientific research, which requires flexibility and imagination. Of course, Fortran is not the best choice for heavy duty object oriented programming, and is not optimal for interacting with the operating system. The philosophy

---

8A Perl motto!
10Java and C++ have been popular choices in computational physics courses. But object oriented programming is usually avoided in the high performance part of a computation. So, one usually uses those languages in a procedural style of programming, cheating herself that she is actually learning the advantages of object oriented programming.
is to let Fortran do what is best for, number crunching, and leave data manipulation and file administration to external, powerful tools. Tools, like awk, shell scripting, gnuplot, Perl and others, are quite powerful and complement all the weaknesses of Fortran mentioned before. The plotting program is chosen to be gnuplot, which provides very powerful tools to manipulate the data and create massive and complicated plots. It can also create publication quality plots and contribute to the “fun part” of the learning experience by creating animations, interactive 3d plots etc. All the tools used in the book are open source software and they are accessible to everyone for free. They can be used in a Linux environment, but they can also be installed and used in Microsoft Windows and Mac OS X.

The other hard part in teaching computational physics to scientists and engineers is to explain that the approach of solving a problem numerically is quite different from solving it analytically. Usually, students of this level are coming with a background in analysis and fundamental physics. It is hard to put them into the mode of thinking about solving a problem using only additions, multiplications and some logical operations. The hardest part is to explain the discretization of a model defined analytically, which can be done in many ways, depending on the accuracy of the approximation. Then, one has to extrapolate the numerical solution, in order to obtain a good approximation of the analytic one. This is done step by step in the book, starting with problems in simple motion and ending with discussing finite size scaling in statistical physics models in the vicinity of a continuous phase transition.

The book comes together with additional material which can be found at the web page of the book¹¹. The accompanying software contains all the computer programs presented in the book, together with useful tools and programs solving some of the exercises of each chapter. Each chapter has problems complementing the material covered in the text. The student needs to solve them in order to obtain hands on experience in scientific computing. I hope that I have already stressed enough that, in order for this book to be useful, it is not enough to be read in a café or in a living room, but one needs to do what it says.

Hoping that this book will be useful to you as a student or as an instructor, I would like to ask you to take some time to send me feedback for improving and/or correcting it. I would also appreciate fan mail or, if you are an expert, a review of the book. If you use the book in a class, as a main textbook or as supplementary material, I would also be

¹¹www.physics.ntua.gr/~konstant/ComputationalPhysics/
thrilled to know about it. Send me email at konstantmail.ntua.gr and let me know if I can publish, anonymously or not, (part of) what you say on the web page (otherwise I will only use it privately for my personal ego-boost). Well, nothing is given for free: As one of my friends says, some people are payed in dollars and some others in ego-dollars!

Have fun computing scientifically!

Athens, 2014.
Chapter 1

The Computer

The aim of this chapter is to lay the grounds for the development of the computational skills which are necessary in the following chapters. It is not an in depth exposition but a practical training by example. For a more systematic study of the topics discussed, we refer to the bibliography. Many of the references are freely available in the web.

There are many choices that one has to make when designing a computer project. These depend on the needs for numerical efficiency, on available programming hours, on the needs for extensibility and upgradability and so on. In this book we will get the flavor of a project that is mostly scientifically and number crunching oriented. One has to make the best of the available computing resources and have powerful tools available for a productive analysis of the data. Such an environment, found in most of today’s supercomputers, that offers flexibility, dependability, simplicity, powerful tools for data analysis and effective compilers is provided by the family of the Unix operating systems. The GNU/Linux operating system is a Unix variant that is freely available and most of its utilities are open source software. The voluntary work of millions of excellent programmers worldwide has built the most stable, fastest and highest quality software available for scientific computing today. Thanks to the idea of the open source software pioneered by Richard Stallman¹ this giant collaboration has been made possible.

Another choice that we have to make is the programming language, and this is going to be Fortran. Fortran has been built mainly for numerical applications and it has been used by many scientists and engineers because of its efficiency in high performance computing. The language is simple and compilers are able to optimize, parallelize and vectorize the

¹www.stallman.org
code very efficiently. There is a lot of scientific and engineering software available in libraries written in Fortran, which has been used and tested extensively for many years. This is a crucial factor for scientific software, so that it can be trusted to be efficient and free of errors. Fortran is not the best choice for interacting with the operating system or for text processing. This shortcoming can be easily overcome by the use of external tools and Fortran can be left to do what she has been designed for: number crunching. Its structure is simple and can be used both for procedural and object oriented programming, in such a way that, it will not make the life of an inexperienced programmer difficult, and at the same time provide high level, abstract and powerful tools for high performance, modular, object oriented, programming needed in a large and complicated project.

Fortran, as well as other languages like C, C++ and Java, is a language that needs to be compiled by a compiler. Other languages, like perl, awk, shell scripting, Macsyma, Mathematica, Octave, Matlab, . . . , are interpreted line by line. These languages can be simple in their use, but they can be prohibitively slow when it comes to a numerically demanding program. A compiler is a tool that analyzes the whole program and optimizes the computer instructions executed by the computer. But if programming time is more valuable, then a simple, interpreted language can lead to faster results.

Another choice that we make in this book, and we mention it because it is not the default in most Linux distributions, is the choice of shell. The shell is a program that “connects” the user to the operating system. In this book, we will teach how to use a shell to “send” commands to the operating system, which is the most effective way to perform complicated tasks. We will use the shell tcsh, although most of the commands can be interpreted by most popular shells. Shell scripting is simpler in this shell, although shells like bash provide more powerful tools, mostly needed for complicated system administration tasks. That may cause a small inconvenience to some readers, since tcsh is not preinstalled in Linux distributions.

²It is more popular to be called “the command line”, or the “terminal”, or the “console”, but in fact the user interaction is through a shell.
³See www.tcsh.org. On Debian like systems, like Ubuntu, installation is very simple through the software center or by the command sudo apt-get install tcsh.
1.1 The Operating System

The Unix family of operating systems offer an environment where complicated tasks can be accomplished by combining many different tools, each of which performs a distinct task. This way, one can use the power of each tool, so that trivial but complicated parts of a calculation don’t have to be programmed. This makes the life of a researcher much easier and much more productive, since research requires from us to try many things before we understand how to compute what we are looking for.

In the Unix operating system everything is a file, and files are organized in a unique and unified filesystem. Documents, pictures, music, movies, executable programs are files. But also directories or devices, like hard disks, monitors, mice, sound cards etc, are, from the point of view of the operating system, files. In order for a music file to be played by your computer, the music data needs to be written to a device file, connected by the operating system to the sound card. The characters you type in a terminal are read from a file “the keyboard”, and written to a file “the monitor” in order to be displayed. Therefore, the first thing that we need to understand is the structure of the Unix filesystem.

1.1.1 Filesystem

There is at least one path in the filesystem associated with each file. There are two types of paths, relative paths and absolute paths. These are two examples:

```
bin/RungeKutta/rk.exe
/home/george/bin/RungeKutta/rk.exe
```

The paths shown above may refer to the same or a different file. This depends on “where we are”. If “we are” in the directory /home/george, then both paths refer to the same file. If on the other way “we are” in a directory /home/john or /home/george/CompPhys, then the paths refer to two different files. In the last two cases, the paths refer to the files

```
/home/john/bin/RungeKutta/rk.exe
/home/george/CompPhys/bin/RungeKutta/rk.exe
```

⁴Some times two or more paths refer to the same file, or as we say, a file has two or more “links” in the same filesystem, but let’s keep it simple for the moment.
respectively. How can we tell the difference? An absolute path always begins with the / character, whereas a relative path does not. When we say that “we are in a directory”, we refer to a position in the filesystem called the current directory, or working directory. Every process in the operating system has a unique current directory associated with it.

Figure 1.1: The Unix filesystem. It looks like a tree, with the root directory / at the top and branches that connect directories with their parents. Every directory contains files, among them other directories called its subdirectories. Every directory has a unique parent directory, noted by .. (double dots). The parent of the root directory is itself.

The filesystem is built on its root and looks like a tree positioned upside down. The symbol of the root is the character / The root is a directory. Every directory is a file that contains a list of files, and it is connected to a unique directory, its parent directory. Its list of files contains other directories, called its subdirectories, which all have it as their parent directory. All these files are the contents of the directory. Therefore, the filesystem is a tree of directories with the root directory at its top which branch to its subdirectories, which in their turn branch into other subdirectories and so on. There is practically no limit to how
large this tree can become, even for a quite demanding environment⁵.

A path consists of a string of characters, with the characters / separating its components, and refers to a unique location in the filesystem. Every component refers to a file. All, but the last one, must be directories in a hierarchy, from parent directory to subdirectory. The only exception is a possible / in the beginning, which refers to the root directory. Such an example can be seen in figure [1.1].

In a Unix filesystem there is complete freedom in the choice of the location of the files⁶. Fortunately, there are some universally accepted conventions respected by almost everyone. One expects to find home directories in the directory /home, configuration files in the directory /etc, application executables in directories with names such as /bin, /usr/bin, /usr/local/bin, software libraries in directories with names such as /lib, /usr/lib etc.

There are some important conventions in the naming of the paths. A single dot “.” refers to the current directory and a double dot “..” to the parent directory. Similarly, a tilde “~” refers to the home directory of the user. Assume, e.g., that we are the user george running a process with a current directory /home/george/Music/Rock (see figure [1.1]). Then, the following paths refer to the same file /home/george/Doc/lyrics.doc:

```
../../../Doc/lyrics.doc
~/Doc/lyrics.doc
~george/Doc/lyrics.doc
../../Doc/lyrics.doc
```

Notice that ~ and ~george refer to the home directory of the user george (ourselves), whereas ~mary refer to the home directory of another user, mary.

We are now going to introduce the basic commands for filesystem navigation and manipulation⁷. The command cd (=change directory)

---

⁵Of course, the capacity of the filesystem is finite, issue the command “df -i .” in order to see the number of inodes available in your filesystem. Every file corresponds to one and only one inode of the filesystem. Every path is mapped to a unique inode, but an inode maybe pointed to by more than one paths.

⁶This gives a great sense of freedom, but historically this was a important factor that led the Unix operating systems, although superior in quality, not to win a fair share of the market! The Linux family tries to keep things simple and universal to a large extent, but one should be aware that because of this freedom files in different version of Linuxes or Unices can be in different places.

⁷Remember that lines that begin with the > character are commands. All other lines refer to the output of the commands.
changes the current directory, whereas the command `pwd` (=print working directory) prints the current directory:

```
> cd /usr/bin
> pwd
/usr/bin
> cd /usr/local/lib
> pwd
/usr/local/lib
> cd
> pwd
/home/george
> cd ..
> pwd
/usr/local/lib
> cd ../..
> pwd
/usr
```

The argument of the command `cd` is an absolute or a relative path. If the path is correct and we have the necessary permissions, the command changes the current directory to this path. If no path is given, then the current directory changes to the home directory of the user. If the character `-` is given instead of a path, then the command changes the current directory to the previous current directory.

The command `mkdir` creates new directories, whereas the command `rmdir` removes empty directories. Try:

```
> mkdir new
> mkdir new/01
> mkdir new/01/02/03
mkdir: cannot create directory `new/01/02/03': No such file or directory
> mkdir -p new/01/02/03
> rmdir new
rmdir: `new': Directory not empty
> rmdir new/01/02/03
> rmdir new/01/02
> rmdir new/01
> rmdir new
```

Note that the command `mkdir` cannot create directories more than one level down the filesystem, whereas the command `mkdir -p` can. The “switch” `-p` makes the behavior of the command different than the default one.
In order to list the contents of a directory, we use the command `ls` (=list):

```
> ls
BE.eps  Byz.eps  Programs  srBE_xyz.eps  srB_xyz.eps
B.eps  Bzy.eps  srBd_xyz.eps  srB_xyz.eps
> ls Programs
Backup    rk3_Byz.f90  rk3.f90
plot-commands    rk3_Bz.f90  rk3_g.f90
```

The first command is given without an argument and it lists the contents of the current directory. The second one, lists the contents of the subdirectory of the current directory `Programs`. If the argument is a list of paths pointing to regular files, then the command prints the names of the paths. Another way of giving the command is

```
total  252
-rw-r--r--  1  george  users  24284  May 1 12:08  BE.eps
-rw-r--r--  1  george  users  22024  May 1 11:53  B.eps
-rw-r--r--  1  george  users  29935  May 1 13:02  Byz.eps
-rw-r--r--  1  george  users  48708  May 1 12:41  Bzy.eps
drwxr-xr-x  4  george  users  4096  May 1 23:38  Programs
-rw-r--r--  1  george  users  41224  May 1 22:56  srBd_xyz.eps
-rw-r--r--  1  george  users  23187  May 1 21:13  srBE_xyz.eps
-rw-r--r--  1  george  users  24610  May 1 20:29  srB_xy.eps
-rw-r--r--  1  george  users  23763  May 1 20:29  srB_xyz.eps
```

The switch `-l` makes `ls` to list the contents of the current directory together with useful information on the files in 9 columns. The first column lists the permissions of the files (see below). The second one lists the number of links of the files. The third one lists the user who is the owner of each file. The fourth one lists the group that is assigned to the files. The fifth one lists the size of the file in bytes (=8 bits). The next three ones list the modification time of the file and the last one the paths of the files.

File permissions are separated in three classes: owner permissions, group permissions and other permissions. Each class is given three specific permissions, `r`=read, `w`=write and `x`=execute. For regular files, read permission effectively means access to the file for reading/copying, write permission means permission to modify the contents of the file and execute permission means permission to execute the file.

---

*For a directory it means the number of its subdirectories plus 2 (the parent directory and itself). For a regular file, it shows how many paths in the filesystem point to this file.

*See the “File system permissions” entry in en.wikipedia.org.
execute permission means permission to execute the file as a command.¹⁰ For directories, read permission means that one is able to read the names of the files in the directory (but not make it as current directory with the cd command), write permission means to be able to modify its contents (i.e. create, delete, and rename files) and execute permission grants permission to access/modify the contents of the files (but not list the names of the files, this is granted by the read permission).

The command ls -l lists permissions in three groups. The owner (positions 2-4), the group (positions 5-7) and the rest of the world (others - positions 8-10). For example

```
-rw-r--r--
-rwxr-----
drwx--x--x
```

In the first case, the owner has read and write but not execute permissions and the group+others have only read permissions. In the second case, the user has read, write and execute permissions, the group has read permissions and others have no permissions at all. In the last case, the user has read, write and execute permissions, whereas the group and the world have only execute permissions. The first character d indicates a special file, which in this case is a directory. All special files have this position set to a character, while regular files have it set to -. File permissions can be modified by using the command chmod:

```
> chmod u+x file
> chmod og=w file1 file2
> chmod a+r file
```

Using the first command, the owner (u≡ user) obtains (+) permission to execute (x) the file named file. Using the second one, the rest of the world (o≡ others) and the group (g≡group) loose (−) the write (w) permission to the files named file1 and file2. Using the third one, everyone (a≡all) obtain read (r) permission on the file named file.

We will close this section by discussing some commands which are used for administering files in the filesystem. The command cp (copy) copies the contents of files into other files:

```
> cp file1.f90 file2.f90
```

¹⁰Of course it is the user’s responsibility to make sure the file with execute permission is actually a program that is possible to execute. An error results if this is not the case.
1.1. THE OPERATING SYSTEM

If the file file2.f90 does not exist, the first command copies the contents of file1.f90 to a new file file2.f90. If it already exists, it replaces its contents by the contents of the file file2.f90. In order for the second command to be executed, Programs needs to be a directory. Then, the contents of the files file1.f90, file2.f90, file3.f90 are copied to identical files in the directory Programs. Of course, we assume that the user has the appropriate privileges for the command to be executed successfully.

The command mv “moves”, or renames, files:

The first command renames the file file1.f90 to file2.f90. The second one moves files file1.f90, file2.f90, file3.f90 into the directory Programs.

The command rm (remove) deletes files¹¹. Beware, the command is unforgiving: after deletion, a file cannot be restored into the filesystem¹². Therefore, after executing successfully the following commands

the files file1.f90, file2.f90, file3.f90 do not exist in the filesystem anymore. A more prudent use of the command demands the flag -i. Then, before deletion we are asked for confirmation:

¹¹Actually it removes “links” from files. A file may have more than one links in the same partition of a filesystem. A file is deleted when its last link is removed.

¹²This does not mean that its contents have been deleted from the disk. Deletion means marking for overwriting. Until the data is overwritten it can be recovered by the use of special tools. Shredding sensitive data can be tricky business...
When we type y, the file is deleted, when we type n, the file is not deleted.

We cannot remove directories the same way. It is possible to use the command *rmdir* in order to remove *empty* directories. In order to delete directories together with their contents (including subdirectories and their contents) use the command \[\texttt{rm -r}\]. For example, assume that the contents of the directories dir1 and dir1/dir2 are the files:

\[
./\text{dir1} \\
./\text{dir1/file2.f90} \\
./\text{dir1/file1.f90} \\
./\text{dir1/dir2} \\
./\text{dir1/dir2/file3.f90}
\]

Then the results of the following commands are:

\[
> \texttt{rm dir1} \\
\texttt{rm: cannot remove ‘dir1’: Is a directory} \\
> \texttt{rm dir1/dir2} \\
\texttt{rm: cannot remove ‘dir1/dir2’: Is a directory} \\
> \texttt{rmdir dir1} \\
\texttt{rmdir: dir1: Directory not empty} \\
> \texttt{rmdir dir1/dir2} \\
\texttt{rmdir: dir1/dir2: Directory not empty} \\
> \texttt{rm -r dir1}
\]

The last command removes all files (assuming that we have write permissions for all directories and subdirectories). Alternatively, we can empty the contents of all directories first, and then remove them with the command *rmdir*:

\[
> \texttt{cd dir1/dir2; rm file3.f90} \\
> \texttt{cd .. ; rmdir dir2} \\
> \texttt{rm file1.f90 file2.f90} \\
> \texttt{cd .. ; rmdir dir1}
\]

Note that by using a semicolon, we can execute two or more commands on the same line.

\[\text{\footnotesize \textsuperscript{13}A small mistake, like \texttt{rm -rf * and your data is ... history!}}\]
1.1.2 Commands

Commands in a Unix operating system are files with execute permission. When we write a sentence on the command line, like

```
> ls -l test.f90 test.dat
```

the shell reads its and interprets it. The shell is a program that creates a interface between a user and the operating system. The first word (ls) of the sentence is interpreted as a command. The rest of the words are the arguments of the command and the program can use them (or not) at the discretion of its programmer. There is a special convention for arguments that begin with a - (e.g. -l, --help, --version, -03). They are called options or switches, and they act as virtual switches that make the program act in a particular way. We have already seen that the program ls gives a different output with the switch -l.

In order for a command to be executed, the shell looks for a file that has the same name as the command (here a file named ls). In order to understand where the shell looks for such a file, we should digress a little bit and explain the use of shell variables and environment variables. These have a name, which is a string of permissible characters, and their values are obtained by preceding their name with the $ character. For example the variable PATH has value $PATH. The values of the environment variables can be set with the command setenv and of the shell variables with the command set:

```
> setenv MYVAR test-env
> set myvar = test-shell
> echo $MYVAR $myvar
```

Two special variables are the variables PATH and path:

```
>echo $PATH
/usr/local/bin:/usr/bin:/bin:/usr/X11/bin
>echo $path
/usr/local/bin /usr/bin /bin /usr/X11/bin
```

The first one is an environment variable and the second one is a shell variable. Their values are set by the shell, and we don’t need to worry

---

"The command setenv is special to the tcsh shell. For example the bash shell uses the syntax MYVAR=test-env in order to set the value of an environment variable."
about them, unless we want to change them. Their value is a string of characters whose components should be valid paths to directories. In the first case, the components are separated by a : , while in the second case, by one or more spaces. In the example shown above, the shell searches each component of the path or PATH variables (in this order) until it finds a file ls in their contents. If it succeeds and the file has execute permissions, then the program in this file is executed. If it fails, then it prints an error message. Try the commands:

```
> which ls
/bin/ls
> ls -l /bin/ls
-rw-r-xr-x 1 root root 93560 Sep 28 2006 /bin/ls
```

We see that the program that the ls command executes the program in the file /bin/ls.

The arguments of a command are passed on to the program that the command executes for possible interpretation. For example:

```
> ls -l test.f90 test.dat
```

The argument -l is the switch that results in a long listing of the files. The arguments test.f90 and test.dat are interpreted by the program ls as paths that it will look up for file information.

You can use the * ( wildcard) character as a shorthand notation for a group of files. For example, in the command shown below

```
> ls -l *.f90 *.dat
```

the shell will expand *.f90 and *.dat to a list of all files whose names end with .f90 or .dat. Therefore, if the current directory contains the files test.f90, test1.f90, myprog.f90, test.dat, hello.dat, the arguments that will be passed on to the command ls are

```
> ls -l myprog.f90 test1.f90 test.f90 hello.dat test.dat
```

For each command there are three special files associated with it. The first one is the standard input ( stdin), the second one is the standard output ( stdout) and the third one the standard error ( stderr). These are files where the program can print or read data from. By default, these files are the terminal that the user uses to execute the command. In this case,
1.1. THE OPERATING SYSTEM

when the program reads data from the stdin, then it reads the data that we type to the terminal using the keyboard. When the program writes data to the stdout or to the stderr, then the data is written to the terminal.

The advantage of using these special files in order to read/write data is that the user can redirect the input/output to these files to any file she wants. Using the character > at the end of a command redirects the stdout to the file whose name is written after >. For example:

```
> ls
file1.f90 file2.f90 file3.f90 file4.csh
> ls > results
> ls
file1.f90 file2.f90 file3.f90 file4.csh results
```

The first of the above commands, prints the contents of the current working directory to the terminal. The second command redirects data written to the stdout to the file results. After executing the command, the file results is created and its contents are the names of the files file1.f90 file2.f90 file3.f90 file4.csh. If the file results does not exist (as in the above example), the file is created. If it already exists, it is truncated and its contents replaced by the data written to the stdout of the command. If we want to append data without erasing the existing contents, then we should use the string of characters >>. Therefore, if we give the command

```
> ls >> results
```

after executing the previous commands, then the contents of the file results will be

```
file1.f90 file2.f90 file3.f90 file4.csh
file1.f90 file2.f90 file3.f90 file4.csh results
```

The redirection of the stdin is accomplished by the use of the character < while that of the stderr by the use of the string of characters ^&. We will see more examples in section 1.2.

It is possible to redirect the stdout of a command to be the stdin of another command. This is very useful for creating filters. A filter is

\[15\]This syntax is particular to the tcsh shell. For other shells (bash, sh, ...) read their documentation.
a command that creates a flow of data between two or more programs. This process is called "piping." Pipes are created by using the character `|`

```bash
> cmd1 | cmd2 | cmd3 | ... | cmdN
```

Using the syntax shown above, the stdout of the command `cmd1` is redirected to the stdin of the command `cmd2`, the stdout of the command `cmd2` is redirected to the stdin of the command `cmd3` etc. More examples will be presented in section 1.2.

### 1.1.3 Looking for Help

Unix got itself a reputation for not being user friendly. This is far from the truth. Although there is a steep learning curve, detailed documentation for almost everything is available online.

The key for a comfortable ride is to learn how to use the help system available on your computer and on the internet. Most of the commands are self documented. A simple test, like the one shown below, will help you with the basic usage of most of the commands:

```bash
> cmd --help
> cmd -h
> cmd -help
> cmd -?
```

For example, try the command `ls --help`. For a window application, start from the menu “Help”. You should not be afraid and/or lazy and you should proceed with careful searching and reading.

For example, let’s assume that you have heard about a command that sounds like `printf`, or something like that. The first level of online help is the `man` (=manual) command that searches the “man pages”. Read the output of the command

```bash
> man printf
```

The command `info` usually provides more detailed and user friendly documentation. It has basic browsing capabilities like the browsers you use to read pages from the internet. Try the command

```bash
> info printf
```
Furthermore, the commands

```
> man -k printf
> whatis printf
```

will inform you that there are other, possibly related, commands with names like fprintf, fwprintf, wprintf, sprintf...

```
> whatis printf
printf (1)  - format and print data
printf (1p) - write formatted output
printf (3)  - formatted output conversion
printf (3p) - print formatted output
printf [builtins] (1) - bash built-in commands, see bash
```

The second column printed by the whatis command is the “section” of the man pages. In order to gain access to the information in a particular section, you have to give it as an argument to the man command:

```
> man 1 printf
> man 1p printf
> man 3 printf
> man 3p printf
> man bash
```

Section 1 of the man pages contains information of ordinary command line commands, section 3 contains information on functions in libraries of the C language. Section 2 contains information on commands used for system administration. You may browse the directory /usr/share/man, or read the man page of the man command (use the command man man for that!).

By using the command

```
> printf --help
```

we obtain plenty of memory refreshing information. The command

```
> locate printf
```

shows us many files related to the command printf. The commands
CHAPTER 1. THE COMPUTER

> which printf
> where printf

give information on the location of the executable(s) of the command printf.

Another useful feature of the shell is the command or filename completion. This means that we can write only the first characters of the name of a command or filename and then press simultaneously the keys [Ctrl-d] (i.e. press the key Ctrl and the key of the letter d at the same time). Then the shell will complete the name of the command up to the point that is is unique with the given string of characters.

> pri[Ctrl-d]
priaffenm printf printenv printnode
test

Try to type an x on the command line and then type [Ctrl-d]. You will learn all the commands that are available and whose name begins with an x: xterm, xeyes, xclock, xcalc, ...

Finally, the internet contains a wealth of information. Google your blues... and you will be rewarded!

1.2 Text Processing Tools – Filters

For doing data analysis, we will need powerful tools for manipulating data in text files. These are files that consist solely of printable characters. Some tools that can be used in order to construct complicated and powerful filters are the programs cat, less, head, tail, grep, sort and awk.

Suppose that we have data in a file named data which contains information on the contents of a food warehouse and their prices:

<p>| | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>bananas</td>
<td>100</td>
<td>pieces</td>
<td>1.45</td>
</tr>
<tr>
<td>apples</td>
<td>325</td>
<td>boxes</td>
<td>1.18</td>
</tr>
<tr>
<td>pears</td>
<td>34</td>
<td>kilos</td>
<td>2.46</td>
</tr>
<tr>
<td>bread</td>
<td>62</td>
<td>kilos</td>
<td>0.60</td>
</tr>
</tbody>
</table>

If you use the bash shell press [Tab] once or twice.

Use the same procedure to auto-complete the names of files in the arguments of commands.

The particular file, as well as most of the files in this section, can be found in the accompanying software of the chapter. It is highly recommended that you try all the commands in this section by using all the provided files.
The command

```bash
> cat data
```

prints the contents of the file data to the stdout. In general, this command prints the contents of all files given in its arguments or the stdin if none is given. Since the stdin and the stdout can be redirected, the command

```bash
> cat < data > data1
```

takes the contents of the file data from the stdin and prints them to the stdout, which in this case is the file data1. This command has the same result as the command:

```bash
> cp data data1
```

The command

```bash
> cat data data1 > data2
```

prints the contents of the file data and then the contents of the file data1 to the stdout. Since the stdout is redirected to the file data2, data2 contains the data of both files.

By giving the command

```bash
> less gfortran.txt
```

you can browse the data contained in the file gfortran.txt one page at a time. Press [space] in order to “turn” a page, [b] to turn back a page. Press the up and down arrows to move one line backwards/forward. Press [g] in order to jump to the beginning of the file and press [G] in order to jump to the end. Press [h] in order to get a help message and press [q] in order to quit.

The commands

```bash
> head \-n 1 data
bananas 100 pieces 1.45
> tail \-n 2 data
```
print the first line, the last two lines and the second to the last line of the file data to the stdout respectively. Note that, by piping the stdout of the command tail to the stdin of the command head, we are able to construct the filter “print the line before the last one”. The command sort sorts the contents of a file by comparing each line of its text with all others. The sorting is alphabetical, unless otherwise set by using options. For example

```
> sort data
apples 325 boxes 1.18
bananas 100 pieces 1.45
bread 62 kilos 0.60
ham 85 kilos 3.56
pears 34 kilos 2.46
```

For reverse sorting, try `sort -r data`. We can also sort by comparing specific fields of each line. By default, fields are words separated by one or more spaces. For example, in order to sort w.r.t. the second column of the file data, we can use the switch `-k 2` (=second field). Furthermore, we can use the switch `-n` for numerical sorting:

```
> sort -k 2 -n data
pears 34 kilos 2.46
bread 62 kilos 0.60
ham 85 kilos 3.56
bananas 100 pieces 1.45
apples 325 boxes 1.18
```

If we omit the switch `-n`, the comparison of the lines is performed based on character sorting of the second field and the result is

```
> sort -k 2 data
bananas 100 pieces 1.45
apples 325 boxes 1.18
pears 34 kilos 2.46
bread 62 kilos 0.60
ham 85 kilos 3.56
```
The last column contains floating point numbers (not integers). In order to sort by the values of such numbers we should use the switch \texttt{-g}:

\begin{verbatim}
> sort \(-k 4 \-g\) data
bread 62 kilos 0.60
apples 325 boxes 1.18
bananas 100 pieces 1.45
pears 34 kilos 2.46
ham 85 kilos 3.56
\end{verbatim}

The command \texttt{grep} processes a text file line by line, searching for a given string of characters. When this string is found anywhere in a line, this line is printed to the stdout. The command

\begin{verbatim}
> grep kilos data
pears 34 kilos 2.46
bread 62 kilos 0.60
ham 85 kilos 3.56
\end{verbatim}

prints each line containing the string “kilos”. If we want to search for all line \textit{not} containing the string “kilos”, then we add the switch \texttt{\textasciitilde v}:

\begin{verbatim}
> grep \textasciitilde v kilos data
bananas 100 pieces 1.45
apples 325 boxes 1.18
\end{verbatim}

We can use a regular expression for searching a whole family of strings of characters. These monsters need a full book for discussing them in detail! But it is not hard to learn how to use some simple forms of regular expressions. Here are some examples:

\begin{verbatim}
> grep \^b data
bananas 100 pieces 1.45
bread 62 kilos 0.60
> grep ‘0$’ data
bread 62 kilos 0.60
> grep ‘3\[24\]’ data
apples 325 boxes 1.18
pears 34 kilos 2.46
\end{verbatim}

The first one, prints each line whose first character is a \texttt{b}. The second one, prints each line that ends with a \texttt{0}. The third one, prints each line containing the strings \texttt{32 or 34}.
By far, the strongest tool in our toolbox is the awk program. By default, awk analyzes a text file line by line. Each word (or field in the awk jargon) of these lines is stored in a set of variables with names $1, $2, .... The variable $0 contains the full line currently processed, whereas the variable NF counts the number of fields in the current line. The variable NR counts the number of lines of the file processed so far by awk.

An awk program can be written in the command line. A set of commands within { ... } is executed for each line of input. The constructs BEGIN{ ... } and END{ ... } contain commands executed, only once, before and after the processing of the file respectively. For example, the command

```
> awk '{print $1,"total value= ",$2*$4}' data
```

prints the name of the product (1st column = $1) and the total value stored in the warehouse (2nd column = $2) \times (4th column = $4). More examples are given below:

```
> awk '{value += $2*$4}END{print "Total= ",$value}' data
Total= 951.94
> awk '{av += $4}END{print "Average Price= ",$av/NR}' data
Average Price= 1.85
> awk '{print $2^2 * sin($4) + exp($4)}' data
```

The first one calculates the total value of all products: The processing of each line results in the increment (+=) of the variable value by the product of the second and fourth fields. In the end (END{ ... }), the string Total= is printed, together with the final value of the variable value. This is an easy way for computing the sum of the values calculated for each line. The second command, calculates and prints an average. The sum is calculated in each line and stored in the variable av. In the end, we print the quotient of the sum of all values by the number of lines that have been processed (NR). The last command shows a (crazy) mathematical expression based on numerical values found in each line of the file data: It computes the square of the second field times the sine of the fourth field plus the exponential of the fourth field.
There is much more potential in the commands presented above. Reading the documentation and getting experience by using them will provide you with very strong tools in order to accomplish complicated tasks.

1.3 Programming with Emacs

For a programmer that spends many hours programming every day, the environment and the tools available for editing the commands of a large and complicated program determine, to a large extent, the quality of her life! An editor edits the contents of a text file, that consists solely of printable characters. Such editors, available in most Linux environments, are the programs gedit, vim, pico, nano, zile... They provide basic functionality such as adding, removing or changing text within a file as well as more complicated functions, such as copying, pasting, searching and replacing text etc. There are many functions that are particularly useful to a programmer, such as detecting and formatting keywords of a particular programming language, pretty printing, closing scopes etc, which can be very useful for comfortable programming and for spotting errors. A very powerful and “knowledgeable” editor, offering many such functions for several programming languages, is the GNU Emacs editor¹⁹. Emacs is open source software, it is available for free and can be used in most available operating systems. It is programmable²⁰ and the user can automate most of her everyday repeated tasks and configure it to her liking. There is a full interaction with the operating system, in fact Emacs has been built with the ambition of becoming an operating system. For example, a programmer can edit a Fortran file, compile it, debug it and run it, everything done with Emacs commands.

1.3.1 Calling Emacs

In the command line type

```
> emacs &
```

¹⁹http://www.gnu.org/software/emacs/ (main site),
(general info)

²⁰Emacs is written in a dialect of the programming language Lisp, called Elisp. There is no need of an in-depth knowledge of the language in order to program simple functions, just see how others are doing it...
Note the character & at the end of the line. This makes the particular command to run in the background. Without it, the shell waits until a command exits in order to return the prompt.

In a desktop environment, Emacs starts in its own window. For a quick and dirty editing session, or in the case that a windows environment is not available, we can run Emacs in a terminal mode. Then, we omit the & at the end of the line and we run the command:

```
> emacs --nw
```

The switch --nw forces Emacs to run in terminal mode.

Figure 1.2: The Emacs window in a windows environment. The buttons of very basic functions found on its toolbar are shown and explained.

---

²¹Quite handy when we edit files in a remote computer.
1.3. PROGRAMMING WITH EMACS

Figure 1.3: Emacs in a non-window mode running on the console. In this figure, we have typed the command `save-buffers-kill-emacs` in the minibuffer, a command that exits Emacs after saving edited data from all buffers. The same command can be given using the keyboard shortcut `C-x C-c`. We can see the mode line and the name of the buffer `toy.f` written on it, the percentage of the buffer (6%) shown in the window, the line and columns (33,0) where the point lies and the editing mode which is active on the buffer (Fortran mode (Fortran), Abbreviation mode (Abbrev), Auto Fill mode (Fill)).

1.3.2 Interacting with Emacs

We can interact with Emacs in various ways. Newbies will prefer buttons and menus that offer a simple and intuitive interface. For advanced usage, however, we recommend that you make an effort to learn the keyboard shortcuts. There are also thousands of functions available to be used interactively. They are called from a “command line”, called the minibuffer in the Emacs jargon.

Keyboard shortcuts are usually combinations of keystrokes that consist of the simultaneous pressing of the Ctrl or Alt keys together with other keys. Our convention is that a key sequence starting with a `C-` means that the characters that follow are keys simultaneously pressed with the Ctrl key. A key sequence starting with a `M-` means that the
characters that follow are keys simultaneously pressed with the Alt key. Some commands have shortcuts consisting of two or more composite keystrokes. For example by C-x C-c we mean that we have to press simultaneously the Ctrl key together with x and then press simultaneously the Ctrl key together with c. This sequence is a shortcut to the command that exits Emacs. Another example is C-x 2 which means to press the Ctrl key together with x and then press only the key 2. This is a shortcut to the command that splits a window horizontally to two equal parts.

The most useful shortcuts are M-x (press the Alt key simultaneously with the x key) and C-g. The first command takes us to the minibuffer where we can give a command by typing its name. For example, type M-x and then type save-buffers-kill-emacs in the minibuffer (this will terminate Emacs). The second one is an “SOS button” that interrupts anything Emacs does and returns control to the working buffer. This can be pretty handy when a command hangs or destroys our work and we need to interrupt it.

The conventions for the mouse events are as follows: With Mouse-1, Mouse-2 and Mouse-3 we denote a simple click with the left, middle and right buttons of the mouse respectively. With Drag-Mouse-1 we mean to press the left button of the mouse and at the same time drag the mouse.

We summarize the possible ways of giving a command in Emacs with the following examples that have the same effect: Open a file and put its contents in a buffer for editing.

- By pressing the toolbar button that looks like a white sheet of paper (see figure 1.2).
- By choosing the File→Visit New File menu entry.
- By typing the keyboard shortcut C-x C-f.
- By typing the name of the command in the minibuffer: M-x find-file

The number of available commands increases from the top to the bottom of the above list.

### 1.3.3 Basic Editing

In order to edit a file, Emacs places the contents of a file in a buffer. Such a buffer is a chunk of computer memory where the contents of the file

---

²²Actually, M- is the so called Meta key, usually bound to the Alt key. It is also bound to the Esc and C-[ keys. The latter can be our only choices available in dumb terminals.
1.3. PROGRAMMING WITH EMACS

Figure 1.4: The basic menus found in Emacs when run in a desktop environment. We can see the basic commands and the keyboard shortcut reminders in the parentheses. E.g. the command File → Visit New File can be given by typing \texttt{C-x C-f}. Note the commands File → Visit New File (open a file), File → Save (write contents of a buffer to a file), File → Exit Emacs, File → Split Window (split window in two), File → New Frame (open a new Emacs desktop window) and of course the well known commands \texttt{Cut}, \texttt{Copy}, \texttt{Paste}, \texttt{Undo} from the Edit menu. We can choose different buffers from the menu Buffers, which contain the contents of other files that we have opened for editing. We recommend trying the Emacs Tutorial and Read Emacs Manual in the Help menu.

are copied and it is not the file itself. When we make changes to the contents of a buffer, the file remains intact. For our changes to take effect and be written to the file, we have to save the buffer. Then, the contents of the buffer are written back to the file. It is important to understand the following cycle of events:

- Read a file’s contents to a buffer.
- Edit buffer contents.
- Write (save) buffer’s contents back into the file.

Emacs may have more than one buffers open for editing simultaneously. By default, the name of the buffer is the same as the name of the file...
that is edited, although this is not necessary\footnote{The user can change the name of the buffer without affecting the name of the file it edits. Also, if we open more than one files with the same name, emacs gives each buffer a unique name. E.g. if we edit more than one files named index.html then the corresponding buffers are named index.html, index.html<2>, index.html<3>, ... .}. The name of a buffer is written in the modeline of the window of the buffer, as can be seen in figure 1.3.

If Emacs crashes or exits before we save our edits, it is possible to recover (part of) them. There is a command \texttt{M-x recover\textendash{}file} that will guide us through the necessary recovery steps, or we can look for a file that has the same name as the buffer we were editing surrounded by two #. For example, if we were editing the file \texttt{file.f90}, the automatically saved changes can be found in the file \texttt{#file.f90#}. Auto saving is done periodically by Emacs and its frequency can be controlled by the user.

The point where we insert text while editing is called “the point”\footnote{Strictly speaking, the point lies between two characters and not on top of a character. The cursor lies on the character immediately to the right of the point. A point is assigned to every \textit{window}, therefore a buffer can have multiple points, one for each window that displays its contents.}. Each buffer has another position marked by “the mark”. A point and the mark define a “region” in the buffer. This is a part of the text in the buffer where the functions of Emacs can act (e.g. copy, cut, change case, spelling etc.). We can set the region by setting a point and then press \texttt{C-SPC} or give the command \texttt{M-x set\textendash{}mark\textendash{}command}. This defines the current point to be the mark. Then we can move the cursor to another point which will define a region together with the mark that we set. Alternatively we can use \texttt{Drag-Mouse-1} (hold the left mouse button and drag the mouse) and mark a region. The mark can be set with \texttt{Mouse-3}, i.e. with a simple click of the right button of the mouse. Therefore by \texttt{Mouse-1} at a point and then \texttt{Mouse-3} at a different point will set the region between the two points.

We can open a file in a buffer with the command \texttt{C-x C-f}, and then by typing its path. If the file already exists, its contents are copied to a buffer, otherwise a new buffer is created. Then:

- We can browse the buffer’s contents with the Up/Down/Left/Right arrows. Alternatively, by using the commands \texttt{C-n}, \texttt{C-p}, \texttt{C-f} and \texttt{C-b}.

- If the buffer is large, we can browse its contents one page at a time.
by using the Page Up/Page Dn keys. Alternatively, by using the commands C-v, M-v.

- Enter text at the points simply by typing it.
- Delete characters before the point by using the Backspace key and after the point by using the Delete key. The command C-d deletes a forward character.
- Erase all the characters in a line that lie ahead of the point by using the command C-k.
- Open a new line by using Enter or C-o.
- Go to the first character of a line by using Home and the last one by using End. Alternatively, by using the commands C-a and C-e, respectively.
- Go to the first character of the buffer with the key C-Home and the last one with the key C-End. Alternatively, with M-x beginning-of-buffer and M-x end-of-buffer.
- Jump to any line we want: Type M-x goto-line and then the line number.
- Search for text after the point: Press C-s and then the text you are looking for. This is an incremental search and the point jumps immediately to the first string that matches the search. The same search can be repeated by pressing C-s repeatedly.

When we finish editing (or frequently enough so that we don’t loose our work due to an unfortunate event), we save the changes in the buffer, either by pressing the save icon on the toolbar, or by pressing the keys C-s, or by giving the command M-x save-buffer.

1.3.4 Cut and Paste

Use the instructions below for slightly more advanced editing:

- Undo! Some of the changes described below can be catastrophic. Emacs has a great Undo function that keeps in its memory many of the changes inflicted by our editing commands. By repeatedly pressing C-/., we undo the changes we made. Alternatively, we can use C-x u or the menu entry Edit→Undo. Remember that C-g interrupts any Emacs process currently running in the buffer.
• Cut text by using the mouse: Click with \texttt{Mouse-1} at the point before the beginning of the text and then \texttt{Mouse-3} at the point after the end. A second \texttt{Mouse-3} and the region is ... gone (in fact it is written in the “kill ring” and it is available for pasting)!

• Cut text by using a keyboard shortcut: Set the mark by \texttt{C-SPC} at the point before the beginning of the text that you want to cut. Then move the cursor after the last character of the text that you want to cut and type \texttt{C-w}.

• Copy text by using the mouse: Drag the mouse \texttt{Drag-Mouse-1} and mark the region that you want to copy. Alternatively, \texttt{Mouse-1} at the point before the beginning of the text and then \texttt{Mouse-3} at the point after the end.

• Copy text by using a keyboard shortcut: Set the mark at the beginning of the text with \texttt{C-SPC} and then move the cursor after the last character of the text. Then type \texttt{M-w}.

• Pasting text with the mouse: We click the middle button \texttt{Mouse-2} at the point that we want to insert the text from the kill ring (the copied text).

• Pasting text with a keyboard shortcut: We move the point to the desired insertion point and type \texttt{C-y}.

• Pasting text from previous copying: A fast choice is the menu entry \texttt{Edit→Paste from kill manu} and then select from the copied texts. The keyboard shortcut is to first type \texttt{C-y} and then \texttt{M-y} repeatedly, until the text that we want is yanked.

• Insert the contents of a file: Move the point to the desired place and type \texttt{C-x i} and the path of the file. Alternatively, give the command \texttt{M-x insert-file}.

• Insert the contents of a buffer: We can insert the contents of a whole buffer at a point by giving the command \texttt{M-x insert-buffer}.

• Replace text: We can replace text interactively with the command \texttt{M-x query-replace}, then type the string we want to replace, and then the replacement string. Then, we will be asked whether we want the change to be made and we can answer by typing \texttt{y} (yes),

\footnote{If it is a two button mouse, try clicking the left and right buttons simultaneously.}
1.3. PROGRAMMING WITH EMACS

n (no), q (quit the replacements). A , (comma) makes only one
replacement and quits (useful if we know that this is the last change
that we want to make). If we are confident, we can change all
string in a buffer, no questions asked, by giving the command M-x
replace-string.

- Change case: We can change the case in the words of a region with
the commands M-x upcase-region, M-x capitalize-region and
M-x downcase-region. Try it.

We note that cutting and pasting can be made between different windows
of the same or different buffers.

1.3.5 Windows

Sometimes it is very convenient to edit one or more different buffers in
two or more windows. The term “windows” in Emacs refers to regions
of the same Emacs desktop window. In fact, a desktop window running
an Emacs session is referred to as a frame in the Emacs jargon. Emacs
can split a frame in two or more windows, horizontally or/and vertically.
Study figure 1.5 on page 69 for details. We can also open a new frame
and edit several buffers simultaneously. We can manipulate windows
and frames as follows:

- Position the point at the center of the window and clear the screen
  from garbage: C-1 (careful: 1 not 1).
- Split a window in two, horizontally: C-x 2.
- Split a window in two, vertically: C-x 3.
- Delete all other windows (remain only with the current one): C-x
  1.
- Delete the current windows (the others remain): C-x 0.
- Move the cursor to the other window: Mouse-1 or C-x 0.
- Change the size of window: Use Drag-Mouse-1 on the line separ-
  rating two windows (the mode line). Use C-^, C-{ for making a
  change of the horizontal/vertical size of a window respectively.

²⁷Be careful not to start a new Emacs session each time that all you need is a new
frame. A new Emacs process takes time to start, binds computer resources and does
not communicate with a different Emacs process.
• Create a new frame: \texttt{C-x 5 2}.

• Delete a frame: \texttt{C-x 5 0}.

• Move the cursor to a different frame: With \texttt{Mouse-1} or with \texttt{C-x 5 o}.

You can have many windows in a dumb terminal. This is a blessing when a desktop environment is not available. Of course, in that case you cannot have many frames.

1.3.6 Files and Buffers

• Open a file: \texttt{C-x C-f} or \texttt{M-x find-file}.

• Save a buffer: \texttt{C-x C-s} or \texttt{M-x save buffer}. With \texttt{C-x C-c} or \texttt{M-x save-buffers-kill-emacs} we can also exit Emacs. From the menu: File→Save. From the toolbar: click on the save icon.

• Save buffer contents to a different file: \texttt{C-x C-w} or \texttt{M-x write-file}. From the menu: File→Save As. From the toolbar: click on the “save as” icon.

• Save all buffers: \texttt{C-x s} or \texttt{M-x save-some-buffers}.

• Connect a buffer to a different file: \texttt{M-x set-visited-filename}.

• Kill a buffer: \texttt{C-x k}.

• Change the buffer of the current window: \texttt{C-x b}. Also, use the menu Buffers, then choose the name of the buffer.

• Show the list of all buffers: \texttt{C-x C-b}. From the menu: Buffers → List All Buffers. By typing Enter next to the name of the buffer, we make it appear in the window. There are several buffer administration commands. Learn about them by typing \texttt{C-h m} when the cursor is in the Buffer List window.

• Recover data from an edited buffer: If Emacs crashed, do not despair. Start a new Emacs and type \texttt{M-x recover-file} and follow the instructions. The command \texttt{M-x recover-session} recovers all unsaved buffers.
• Backup files: When you save a buffer, the previous contents of the file become a backup file. This is a file whose path is the same as the original’s file with a \~ appended in the end. For example a file test.f90 will have as a backup the file test.f90\~. Emacs has version control, and you can configure it to keep as many versions of your edits as you want.

• Directory browsing and directory administration commands: \texttt{C-x d} or \texttt{M-x dired}. You can act on the files of a directory (open, delete, rename, copy etc) by giving appropriate commands. When the cursor is in the \texttt{dired} window, type \texttt{C-h m} to read the relevant documentation.

1.3.7 Modes

Each buffer can be in different modes. Each mode may activate different commands or editing environment. For example each mode can color keywords relevant to the mode and/or bind keys to different commands. There exist major modes, and a buffer can be in only one of them. There are also minor modes, and a buffer can be in one or more of them. Emacs activates major and minor modes by default for each file. This usually depends on the filename but there are also other ways to control this. The user can change both major and minor modes at will, using appropriate commands.

Active modes are shown in a parenthesis on the mode line (see figures 1.3 and 1.5).

• \texttt{M-x f90-mode}: This mode is of special interest in this book since we will edit a lot of Fortran code. We need it activated in buffers that contain a Fortran program and its most useful characteristics are automatic code alignment by pressing the key \texttt{TAB}, the coloring of Fortran commands, variables and other structural constructs (sub-routines, if statements, do loops, variable declarations, statement labels etc). Another interesting function is the one that comments out a whole region of code, as well as the inverse function.

• \texttt{M-x c-mode}: For files containing programs written in the C language. Related modes are the \texttt{c++-mode}, \texttt{java-mode}, \texttt{perl-mode}, \texttt{awk-mode}, \texttt{python-mode}, \texttt{makefile-mode}, \texttt{octave-mode}, \texttt{gnuplot-mode}, \texttt{mathematica-mode} and others.

• \texttt{latex-mode}: For files containing \LaTeX text formatting commands.
• text-mode: For editing simple text files (.txt).

• fundamental-mode: The basic mode, when one that fits better doesn’t exist...

Some interesting minor modes are:

• M-x auto-fill-mode: When a line becomes too long, it is wrapped automatically. A related command to do that for the whole region is M-x fill-region, and for a paragraph M-x fill-paragraph.

• M-x overwrite-mode: Instead of inserting characters at the point, overwrite the existing ones. By giving the command several times, we toggle between activating and deactivating the mode.

• M-x read-only mode: When visiting a file with valuable data that we don’t want to change by mistake, we can activate this mode so that changes will not be allowed by Emacs. When we open a file with the command C-x C-r or M-x find-file-read-only this mode is activated. We can toggle this mode on and off with the command C-x C-q (M-x toggle-read-only). See the mode line of the buffer jack.c in figure [1.5] which contains a string %% . By clicking on the %% we can toggle the read-only mode on and off.

• flyspell-mode: Spell checking as we type.

• font-lock-mode: Colors the structural elements of the buffer which are defined by the major mode (e.g. the commands of a Fortran program).

In a desktop environment, we can choose modes from the menu of the mode line. By clicking with Mouse-3 on the name of a mode we are offered options for (de)activating minor modes. With a Mouse-1 we can (de)activate the read-only mode with a click on :%% or :-- respectively. See figure [1.5].

1.3.8 Emacs Help

Emacs’ documentation is impressive. For newbies, we recommend to follow the mini course offered by the Emacs tutorial. You can start the tutorial by typing C-h t or select Help → Emacs Tutorial from the menu. Enjoy... The Emacs man page (give the man emacs command in the command line) will give you a summary of the basic options when calling Emacs from the command line.
A quite detailed manual can be found in the Emacs info pages.²⁸ Using info needs some training, but using the Emacs interface is quite intuitive and similar to using a web browser. Type the command C-h r (or choose Help → Emacs Tutorial from the menu) and you will open the front page of the emacs manual in a new window. By using the keys SPC and Backspace we can read the documentation page by page. When you find a link (similar to web page hyperlinks), you can click on it in order to open to read the topic it refers to. Using the navigation icons on the toolbar, you can go to the previous or to the next pages, go up one level etc. There are commands that can be given by typing single characters. For example, type d in order to jump to the main info directory. There you can find all the available manuals in the info system installed on your computer. Type g (emacs) and go to the top page of the Emacs manual. Type g (info) and read the info manual.

Emacs is structured in an intuitive and user friendly way. You will learn a lot from the names of the commands: Almost all names of Emacs commands consist of whole words, separated by a hyphen “-”, which almost form a full sentence. These make them quite long sometimes, but by using auto completion of their names this does not pose a grave problem.

- **auto completion**: The names of the commands are auto completed by typing a TAB one or more times. E.g., type M-x in order to go to the minibuffer. Type capi[TAB] and the command autocompletes to capitalize-. By typing [TAB] for a second time, a new window opens and offers the options for completing to two possible commands: capitalize-region and capitalize-word. Type an extra r[TAB] and the command auto completes to the only possible choice capitalize-region. You can see all the commands that start with an s by typing M-x s[TAB][TAB]. Sure, there are many... Click on the *Completions* buffer and browse the possibilities. A lot will become clear just by reading the names of the commands. By typing M-x [TAB][TAB], all available commands will appear in your buffer!

- **keyboard shortcuts**: If you don’t remember what happens when you type C-s, no problem: Type C-h k and then the ... forgotten key sequence C-s. Conversely, have you forgotten what is the keyboard

²⁸If you prefer books in the form of PDF visit the page www.gnu.org/software/emacs and click on Documentation. You will find a 600 page book that has almost everything!
shortcut of the command save-buffer? Type C-h w and then the command.

- **functions**: Are you looking for a command, e.g. save-something -I-forgot? Type C-h f and then save-[TAB] in order to browse over different choices. Use Mouse-2 in order to select the command you are interested in, or type and complete the rest of its name (you may use [TAB] again). Read about the function in the *Help* buffer that opens.

- **variables**: Do the same after typing C-h v in order to see a variable’s value and documentation.

- **command apropos**: Have you forgotten the exact name of a command? No problem... Type C-h a and a keyword. All commands related to the keyword you typed will appear in a buffer. Use C-h d for even more information.

- **modes**: When in a buffer, type C-h m and read information about the active modes of the buffer.

- **info**: Type C-h i

- Have you forgotten everything mentioned above? Just type C-h ?

### 1.3.9 Emacs Customization

You can customize everything in Emacs. From key bindings to programming your own functions in the Elisp language. The most common way for a user to customize her Emacs sessions, is to put all her customization commands in the file ~/.emacs in her home directory. Emacs reads and executes all these commands just before starting a session. Such a .emacs file is given below:

```elisp
;; Define F1 key to save the buffer
(global-set-key [f1] 'save-buffer)
;; Define Control-c s to save the buffer
(global-set-key \C-cs 'save-some-buffers)
;; Define Meta-s (Alt-s) to interactively search forward
(global-set-key \M-s 'isearch-forward)
;; Define M-x is to interactively search forward
(defun fm() (interactive) (f90-mode))
```
1.4. THE FORTRAN PROGRAMMING LANGUAGE

In this section, we give a very basic introduction to the Fortran programming language. This is not a systematic exposition and you are expected to learn what is needed in this book by example. So, please, if you have not already done it, get in front of a computer and do what you read. You can find many good tutorials and books introducing Fortran in a more complete way in the bibliography.

1.4.1 The Foundation

The first program that one writes when learning a new programming language is the “Hello World!” program. This is the program that prints “Hello World!” on your screen:

```fortran
program hello
    !print a message to the world:
    print *, 'Hello World!' !this is a comment
end program hello
```
Commands, or statements, in Fortran are strings of characters separated by blanks ("words") that we are allowed to write from the 1st to the 132nd column of a file. Each line starts a new command. We can put more than one command on each line by separating them with a semicolon (;). Everything after an exclamation mark (!) is a comment. Proliferation of comments is necessary for documenting our code. Good documentation of our code is an integral part of programming. If the code is planned to be read by others, or by us at a later time, make sure to explain in detail what each line is supposed to do. You and your collaborators will save a lot of time in the process of debugging, improving and extending your code.

The main entry to the program is defined by the command program name, where name can be any string of alphanumeric characters and an underscore. When the program runs, it starts executing commands at this point. The end of the program, as well as of any other program unit (functions, subroutines, modules), is defined by the line end program name.

The first (and only) command given in the above program is the print command. It prints the string of characters "Hello World!" to the stdout. The "*", " is part of the syntax and it is not printed, of course. Fortran does not distinguish capital from small letters, so we could have written PRINT, Print, prINt, ... A string of characters in Fortran is enclosed in single or double quotes ("Hello World!" or "Hello World!" is equivalent).

In order to execute the commands in a program, it is necessary to compile it. This is a job done by a program called the compiler that translates the human language programming statements into binary commands that can be loaded to the computer memory for execution. There are many Fortran compilers available, and you should learn which compilers are available for use in your computing environment. Typical names for Fortran compilers are gfortran, f90, ifort, g95, .... You should find out which compiler is best suited for your program and spend time reading its documentation carefully. It is important to learn how to use a new compiler so that you can finely tune it to optimize the performance of your program.

We are going to use the open source and freely available compiler gfortran, which can be installed on most popular operating systems. The compilation command is:

\[ \text{It is possible to break long lines by putting a \& at the end of each broken line and continue the same command in the next one. More on that later.} \]

\[ \text{http://gcc.gnu.org/fortran/} \]
1.4. THE FORTRAN PROGRAMMING LANGUAGE

The switch `-o` defines the name of the executable file, which in our case is `hello`. If the compilation is successful, the program runs with the command:

```
> gfortran hello.f90 -o hello
```

Now, we will try a simple calculation. Given the radius of a circle we will compute its length and area. The program can be found in the file `area_01.f90`:

```
program circle_area
    PI  = 3.141593
    R   = 4.0
    print *, 'Perimeter = ', 2.0*PI*R
    print *, 'Area   = ', PI*R**2
end program circle_area
```

The first two commands define the values of the variables `PI` and `R`. These variables are of type `REAL`, which are floating point numbers. Fortran has implicit rules that can be used to define the type of variables. By default, variables whose name starts with `i, j, k, l, m, n` are of `INTEGER` type. These are exact whole numbers. All other variables are of type `REAL`. We can override these implicit rules by explicitly declaring the type of a variable or by changing the implicit rules with the use of the `implicit` statement. The following two commands have two effects: Computing the length $2\pi R$ and the area $\pi R^2$ of the circle and printing the results. The expressions $2.0*\pi*R$ and $\pi*R**2$ are evaluated before being printed by the `print` command. The multiplication and raising to a power operators are `*` and `**`, respectively. Note the explicit decimal points at the constants `2.0` and `4.0`. If we write `2` or `4` instead, then these are going to be constants of the `INTEGER` type and by using them

---

31Don’t confuse `REAL` variables with the real numbers. `REAL` variables take values that are finite approximations to real numbers and take values that are a subset of the rational numbers. This approximation becomes better with increasing the amount of memory allocated to `REALs`. In most computing environments, `REALs` are allocated 4 or 8 bytes of memory, in which case they approximate real numbers with, more or less, 7 or 17 significant digits, respectively.
the wrong way we may obtain surprising results. We compile and run the program with the commands:

```fortran
> gfortran area_01.f90 -o area
> ./area
Perimeter= 25.13274
Area= 50.26548
```

We will now try a process that repeats itself for many times. We will calculate the length and area of 10 circles of different radii \( R_i = 1.28 + i \), \( i = 1, 2, \ldots, 10 \). We will store the values of the radii in an array \( R(10) \) of the REAL type. The code can be found in the file area_02.f90:

```fortran
program circle_area

  dimension R(10)
  PI = 3.141593
  R(1) = 2.28
  do i=2,10
    R(i) = R(i-1) + 1.0
  enddo
  do i = 1,10
    perimeter = 2*PI*R(i)
    area = PI*R(i)**2
    print *,i,' R=',R(i),', perimeter=',perimeter
    print *,i,' R=',R(i),', area=',area
  enddo
end program circle_area
```

The command `dimension R(10)` defines an array of length 10. This way, the elements of the array are referred by an index that takes value from 1 to 10. For example \( R(4) \) is the fourth element of the array.

Between the lines

```fortran
do i = 2, 10
  ...
enddo
```

we can write commands that are repeatedly executed while the INTEGER

---

34Try adding the command `print *,2/4, 2.0/4.0` and check the results.
variable $i$ takes values from 2 to 10 with increasing step equal to 1. The command:

$$R(i) = R(i-1) + 1.0$$

defines the $i$-th radius to have a value which is larger by the $(i-1)$-th by 1. For the loop to work correctly, we must define the initial value of $R(1)$, otherwise the final result is undefined. The second loop uses the defined $R$-values in order to do the computation and printing of the results.

Now, we will write an interactive version of the program. Instead of hard coding the values of the radii, we will interact with the user asking her to give her own values. The program will read the 10 values of the radii from the standard input (stdin). The program can be found in the file area_03.f90:

```fortran
program circle_area
  implicit none

  integer, parameter :: N=10
  real , parameter :: PI=3.141593
  real , dimension(N) :: R
  real :: area, perimeter
  integer :: i

  do i=1,N
    print*, 'Enter radius of circle: ', R(i)
    read *, R(i)
    print*, 'i=', i, ', R(i)= ', R(i)
  enddo

  open(UNIT=13, FILE= 'AREA.DAT')
  do i = 1, N
    perimeter = 2*PI*R(i)
    area = PI*R(i)**2
    write(13,*), 'R=' , R(i), 'area=', area, &
          'perimeter=', perimeter
  enddo
```

³³The step can change by adding one more entry to the do line: do $i=0,12,4$ runs the loop for $i=0,4,8,12$, whereas do $i=10,6,-2$ for $i=10,8,6$.

³⁴That means that different compilers and/or runs can give different results.
The first statement in the above program is `implicit none`! This statement deactivates the implicit rules of Fortran, and the programmer is obliged to declare all variables in a program unit. It is highly recommendable that you always use this option. You might spend a little more time typing the declarations, but this effort cannot be compared to the pain looking for bugs due to typos in the names of variables. We will follow this practice throughout the book.

The declarations of the variables follow this statement. The variables `N` and `i` are declared to be of the `INTEGER` type, whereas the variables `PI`, `area`, `perimeter` and `R(N)` are declared to be of the `REAL` type. The variables `PI` and `N` are specified to be parameters. Parameters are given specific values which cannot be changed during the execution of the program.

The array elements `R(i)` are read using the command `read`:

```
read *, R(i)
```

The command `read` reads from the stdin. The user types the values at the terminal and then presses [Enter]. We can read more than one variables with one `read` command.

In order to print data to a file, we have to connect it to a `unit`. Each unit is represented by any number between 0 and 99. Some numbers are reserved for special units. The connection of a unit to a file is done with the `open` command. When this is done, we can write to the file with the command `write(n,*), where `n` is the unit number. When we are done writing to a file we should use the command `close(n)`. Then the unit number is available to be used for a different file. The flow of commands is like

```
open (UNIT=13,FILE='AREA.DAT')
...
write (13,*), ....
... close(13)
```

³⁵Can you see the difference between the names `pl1` and `p11`?
³⁶E.g., 5 is the stdin, 6 is the stdout and 0 is the stderr.
³⁷Try to see what happens when you write to a unit what has not been connected to a file via an open command!
The name of the file is determined by the option \texttt{FILE='AREA.DAT'} of the open statement. Uppercase or lowercase characters in the filename make a difference. The option \texttt{FILE='path'} can use any valid path in the filesystem, provided that we have the necessary permissions.

The line

\begin{verbatim}
write(13,*)(R=.,R(i),\text{area= ',area,&}
\hspace{1em}
\text{perimeter= ',perimeter})
\end{verbatim}

shows us how to continue a line containing a long statement to the next one. We place a & at the end of the line and then continue writing the statement to the next. This can happen up to 39 times.

The next step will be to learn how to define and use functions and subroutines. The program below shows how to define a subroutine \texttt{area_of_circle}, which computes the length and area of a circle of given radius. The following program can be found in the file \texttt{area_04.f90}:

\begin{verbatim}
program circle_area

implicit none

integer, parameter :: N=10
real , parameter :: P=3.141593
real , dimension(N):: R
real :: area, perimeter
integer :: i

do i=1,N
print*,\'Enter radius of circle:\'
read *, R(i)
print*,\'i= \',i,' R(i)= \',R(i)
enddo

open(UNIT=13,FILE='AREA.DAT')

do i = 1,N
   call area_of_circle(R(i),perimeter,area)
   write(13,*)(R=.,R(i),\text{area= ',area,&}
\hspace{1em}
\text{perimeter= ',perimeter})
enddo

close(13)

end program circle_area
\end{verbatim}
The calculation of the length and the area of the circle is performed by the call to the subroutine:

```fortran
subroutine area_of_circle(R,L,A)
   implicit none
   real :: R, L, A
   real, parameter :: PI = 3.141593 , PI2 = 2.0*PI
   L = PI2*R
   A = PI*R*R
   return
end subroutine area_of_circle
```

The command call calls a subroutine and transfers the control of the program within the subroutine. The above subroutine has the arguments (R(i), perimeter, area). The argument R(i) is an input variable. It provides the necessary data to the subroutine in order to perform its computation. The arguments perimeter and area are intended for output. Upon return of the subroutine to the main program, they store the result of the computation. The user of a subroutine must learn how to use its arguments in order to be able to call it in her program. These must be documented carefully by the programmer of the subroutine.

The actual program executed by the subroutine is between the lines:

```fortran
subroutine area_of_circle(R,L,A)
   ...
end subroutine area_of_circle
```

The arguments (R, L, A) must be declared in the subroutine and need not have the same names as the ones that we use when we call it. A change of their values within the subroutine will change the values of the corresponding variables in the calling program\footnote{We say that variables in Fortran are passed to subroutines by reference and not by value as in C.}. Therefore, the statements L=PI2*R and A=PI*R*R change the values of the variables perimeter and area to the desired values. The command return returns the control to the calling program. The parameters PI and PI2 are “private” to the subroutine. Their names and values are invisible outside the subroutine.
Similarly, the variables \( i, N, \ldots \), defined in the main program, are invisible within the subroutine.

We summarize all of the above in a program `trionymo.f90`, which computes the roots of a second degree polynomial:

```fortran
! Program to compute roots of a 2nd order polynomial
! Tasks: Input from user, logical statements,
!        use of functions, stop
!        Accuracy in floating point arithmetic
!        e.g. IF(x.eq.0.0)
! Tests: a,b,c = 1 2 3 D= -8
!        a,b,c = 1 -8 16 D= 0 x1= 4
!        a,b,c = 1 -1 -2 D= 9. x1= 2. x2= -1.
!        a,b,c = 2.3 -2.99 -16.422 x1= 3.4 x2= -2.1
! But: 6.8(x-4.3)**2 = 6.8 x**2 -58.48*x+125.732
!        a,b,c = 6.8 -58.48 125.73199
!        D= 0.000204147349 x1= 4.30105066 x2= 4.29894924
!        a,b,c = 6.8 -58.48 125.732, D= -0.000210891725 < 0!!

program trionymo
implicit none
real :: a, b, c, D
real :: x1, x2
real :: Discriminant

print*, 'Enter a,b,c:
read *, a, b, c

! Test if we have a well defined polynomial of 2nd degree:
if( a .eq. 0.0) stop 'trionymo: a=0'

! Compute the discriminant (= diakrinousa)
D = Discriminant(a, b, c)
print *, 'Discriminant: D= ', D

! Compute the roots in each case: D>0, D=0, D<0 (no roots)
if(D .gt. 0.0) then
  call roots(a, b, c, x1, x2)
  print *, 'Roots: x1= ', x1, ' x2= ', x2
else if (D .eq. 0.0) then
  call roots(a, b, c, x1, x2)
  print *, 'Double Root: x1= ', x1
else
  print *, 'No real roots'
```

```
The program reads the coefficients of the polynomial $ax^2 + bx + c$. After
a check whether $a \neq 0$, it computes the discriminant $D = b^2 - 4ac$ by
calling the function Discriminant(a,b,c). The only difference between
a function and a subroutine is that the first one returns a value of a
given type. We don’t need to use the command call in order to run
the commands of a function, this is done by computing its value in an
expression. The type of the value returned must be declared both in the
program that uses the function (real :: Discriminant) and at the entry
point of its program unit (real function Discriminant(a,b,c)). The
value returned to the calling program is the one assigned to the variable
that has the same name as the function:

```fortran
real function Discriminant(a,b,c)
  ...
  Discriminant = b**2 - 4.0 * a * c
  ...
end function Discriminant
```

Notice the use of the comparison operators .gt. (strictly greater than)
and .eq. (equal to):

```fortran
if (D .gt. 0.0 )then
  ...
else if (D .eq. 0.0) then
  ...
else
  ...
endif
```

### 1.4.2 Details

You may skip this paragraph during a first reading of the book. It is
intended mainly to be a reference when reading the later chapters.

There are more types of variables built in Fortran. In the program
listed below, we show how to use CHARACTER variables, floating point
numbers of double precision REAL(8) and complex numbers of single
and double precision, COMPLEX and COMPLEX(8) respectively:

```fortran
program f90_vars
  implicit none

  character(100) :: string

  real(4) :: x !single precision, same as real :: x
  real(8) :: x8 !equivalent to: double precision x8
  !real(16) :: x16 !may not be supported by all compilers
```

³⁹Other operators are .lt., .ge., .le. (strictly less, greater or equal, less or equal),
.ne. (not equal) and .or., .and., .not. (logical or, and and negation).
CHAPTER 1. THE COMPUTER

Complex Numbers:

```plaintext
complex(4) :: z  ! single precision, same as complex :: z
complex(8) :: z8  ! double precision
```

A string: a character array:

```plaintext
string = 'Hello World!'  ! string smaller size, leaves blanks
        ! TRIM: trim blanks
print *, 'A string :: ', string, ': ', TRIM(string), ':
print *, 'join them :: ', string  // string : ''
print *, 'join them :: ', TRIM(string)  // TRIM(string) :
```

Reals with increasing accuracy: Determine PI = 3.14159...

```plaintext
x = 4.0 * atan(1.0)
```

Use D for double precision exponent

```plaintext
x8 = 4.0D0 * atan(1.0D0)
```

Use Q for quadriple precision exponent

```plaintext
x16 = 4.0Q0 * atan(1.0Q0)
```

Complex numbers: single precision

```plaintext
z = (2.0, 1.0)*cexp((3.0, -1.0))
print *, 'z = ', z,  '  Re(z)= ', REAL(z), '  Im(z)= ', IMAG(z), &
        '  |z|= ', ABS(z), '  z*= ', CONJG(z)
```

Complex numbers: double precision

```plaintext
z8 = (2.0D0, 1.0D0)*cdexp((3.0D0, -1.0D0))
print *, 'z = ', z8,  '  Re(z)= ', DBLE(z8), '  Im(z)= ', DIMAG(z8), &
        '  |z|= ', CDABS(z8), '  z*= ', DCONJG(z8)
```

Some interesting points of the program above are:

- The number K in the declaration REAL(K):: x refers to the number of bytes allocated to the variable x. For K=4 we have single precision (same as REAL), for K=8 double precision and for K=16 quadruple precision. The latter is not always available. In the declarations COMPLEX(K), K refers to the number of bytes allocated to the real and imaginary parts of the complex number.

- We always use the exponent notation D in double precision constants, even if the exponent 0. Otherwise the constants are of single precision and we loose the desired accuracy.
• When we want to state the precision of the return value of an intrinsic function explicitly, we usually add a `d` at the beginning of its name (e.g. `exp→dexp, ABS→DABS`). When we want to use the complex version of a function, we usually add a `c` at the beginning of its name (e.g. `exp→cexp, ABS→CABS`). Modify the program in order to achieve higher accuracy in the calculation of $\pi$ and $z = (2+i)e^{3+i}$, by using double precision variables.

• The maximum number of characters in the CHARACTER variable string is 100, and this is declared by the statement `CHARACTER(100)`.

• When we print a CHARACTER variable, all its characters are printed, including trailing blanks. This is very annoying and we can use the function `TRIM` in order to remove them.

• The operator // joins two CHARACTER variables or constants. Notice the effect of the function `TRIM` in the above program.

Another important point to discuss is how to be able to access the same variables from different program units. So far, we simply mentioned that variables have a scope within each function and subroutine. If we wish to have access to the same location of memory from different program units, then we use the common block. See the following example:

```fortran
program f90_common
  implicit none
  real :: k1=1.0, k2=1.0, k3=1.0
  common /CONSTANTS/k1, k2
  print *, 'main: k1= ', k1, ', k2= ', k2, ', k3= ', k3
  call s1 !prints k1 and k2 but not k3
  call s2 !changes the value of k2 but not k3
  print *, 'main: k1= ', k1, ', k2= ', k2, ', k3= ', k3
end program f90_common
```

Common blocks are supposed to be obsolescent in Fortran and programmers are encouraged to avoid them and use modules instead. Due to their simplicity and popularity we will show their usage and also use them in this book.
The common block has the name **CONSTANTS** and we can refer to it from any program unit. Each program unit that uses this common block must use the same declaration, although the names of variables are allowed to be different. The common block **CONSTANTS** points to the same location in the computer memory, where we expect to find the values of two real variables. These variables (k1 and k2) are used and have their values changed in the subroutines s1 and s2. The variable k3, is a different variable in each program unit. The program prints

<table>
<thead>
<tr>
<th>main:</th>
<th>k1= 1.000000</th>
<th>k2= 1.000000</th>
<th>k3= 1.000000</th>
</tr>
</thead>
<tbody>
<tr>
<td>s1:</td>
<td>k1= 1.000000</td>
<td>k2= 1.000000</td>
<td>k3= -2.8117745E-05</td>
</tr>
<tr>
<td>main:</td>
<td>k1= 1.000000</td>
<td>k2= 2.000000</td>
<td>k3= 1.000000</td>
</tr>
</tbody>
</table>

One of the weaknesses of Fortran is that it does not have a convenient control for Input/Output (I/O). For complicated I/O and text manipulation we will use other programs that can do a better job, like **awk**, **perl**, shell scripting, or programs written in **C/C++**. It is important to know some details about I/O commands in Fortran, mainly the specifications that control the accuracy of printed floating point numbers. So far, I/O commands, like **print**, **write**, **read**, used a * in order to control the printing of numbers. But we can replace the * with explicit format directives as follows:

<table>
<thead>
<tr>
<th>program f90_format1</th>
</tr>
</thead>
<tbody>
<tr>
<td>implicit none</td>
</tr>
<tr>
<td>integer :: i</td>
</tr>
<tr>
<td>real :: x</td>
</tr>
<tr>
<td>real, dimension(10) :: a</td>
</tr>
<tr>
<td>real(8) :: x8</td>
</tr>
</tbody>
</table>
1.4. THE FORTRAN PROGRAMMING LANGUAGE

```fortran
i = 123456
x = 2.0 * atan2(1.0,0.0)
print '(A5,I6,F12.7)', x, i = ',i,x
x8 = 2.0D0*atan2(1.0D0,0.0D0)
write (6, '(F18.16,E24.17,G24.17,G24.17)') x8, x8, &
    1.0D15*x8, 1.0D18*x8
write (6, '(3F20.16)') x8, x8/2.0, cos(x8)
write (6, '(200F12.6)')(a(i), i=1,10)
end program f90_format1
```

Note the parentheses within the single quotes: `(A5,I6,F12.7)` is a format directive for the print statement. The A is for printing a CHARACTER, the I for printing an INTEGER and the F for printing a floating point number. The numbers after the letter declare the number of spaces used for printing each one. Beware! If the printing space is not enough, Fortran will not print and you will find a series of * in place of the value of your result! Bummer... In order to estimate the number of spaces needed for a floating point number, you have to include the space taken by the decimal point, the sign, the exponent character, the sign of the exponent and the digits needed for the exponent. Plus a space to separate the numbers in between... So, be generous and give plenty of printing space. In the example shown above, A5 denotes a character of 5 spaces, I6 and integer of 6 spaces and F12 a floating point number of 12 spaces. The decimal point in F12.7 means that we want a floating point with the accuracy of 7 significant digits.

The format directive `(F18.16,E24.17,G24.17,G24.17)` shows how to print double precision variables. These provide an accuracy of 16-17 significant digits and there is no need for keeping more digits. The command E prints a number in scientific form with an exponent. The command G prints the exponent when it is needed. The numbers before the letters denote multiplicity. Therefore 3F20.16 instructs the printing of 3 floating point numbers by reserving 20 spaces and using 16 significant digits for each one of them.

The command `write(6, '(200F12.6)')(a(i), i=1,10)` shows how to print a large array using an implicit loop. We used many more spaces than actually needed (200F12.16) which is OK. If the array gets larger by increasing the range of i, then we will have enough room for printing in the same line. The program prints (we have folded the long line in order to make it visible):

```
x,i= 123456  3.1415927
3.1415926535897931 0.31415926535897931E+01  3141592653589793.0
```
We can organize the format commands by using the FORMAT statement. Then, we use labeled statements in order to refer to them. Labels are numbers put in the beginning of a line which should be unique to a program unit and are within the range 1-99999. We can transfer the control of the program to such a line with a goto command or by using the label in the I/O statements print, write and read as in the example shown below:

```
program f90_format2
  implicit none
  integer i
  real x, a(10)
  real*8 x8

  i = 123456
  x = 2.0 * atan2(1.0,0.0)
  print 100, 'x, i=' , i , x
  x8 = 2.0D0*atan2(1.0D0,0.0D0)
  write(6,123) x8, x8, &
    1.0D15*x8, 1.0D18*x8
  write(6,4444) x8, x8/2.0, cos(x8)
  write(6,9999)(a(i), i=1,10)
  100 FORMAT(A5, I6, F12.7)
  123 FORMAT(F18.16, E24.17, G24.17, G24.17)
  4444 FORMAT(3F20.16)
  9999 FORMAT(200F12.6)
end program f90_format2
```

The reader should also study the Fortran intrinsic functions shown in table 1.2, page 71.

### 1.4.3 Arrays

You may skip this section during the first reading of this book. It will be useful to come back here later.

Arrays are related data of the same type which can be accessed by using one or more indices. For example, after a declaration `real, dimension(10) :: A`, the expressions

```
A(1), A(2), ... , A(10)
```
refer to its 10 real values. The indices can be integer expressions, for example

\[
A(i), B(2*i+3), C(INT(x+y(j)))
\]

where in the last case we used the integer value of the intrinsic function \( \text{INT}(x) \), which returns the integer part of \( x \). Note that, arrays and functions enclose indices and arguments between parentheses \( (...) \) which are of the same style, and the compiler must look at their declarations in order to tell the difference. Examples of array declarations are

\[
\begin{align*}
\text{real, dimension(10)} & :: a, b \\
\text{real, dimension(20)} & :: c, d
\end{align*}
\]

which declare the arrays \( a, b, c, d \), which are of the real kind, with elements \( a(1) \ldots a(10), b(1) \ldots b(10), c(1) \ldots c(20) \) and \( d(1) \ldots d(20) \). An equivalent declaration is

\[
\begin{align*}
\text{real} & :: a(10), b(10), c(20), d(20)
\end{align*}
\]

or

\[
\begin{align*}
\text{integer, parameter} & :: n1 = 10, n2 = 20 \\
\text{real, dimension(n1)} & :: a, c(n2) \\
\text{real} & :: b(n1), d(n2)
\end{align*}
\]

In the last form, we show how to use constant parameters for declaring the size of arrays. For the declarations shown above, the lower bound of all arrays is 1 and the upper bound for \( a \) and \( b \) is 10 and for \( c \) and \( d \) is 20. The upper and lower bound of arrays can be explicitly determined. The declarations

\[
\begin{align*}
\text{integer, parameter} & :: n1 = 10, n2 = 20 \\
\text{real, dimension(0:n1)} & :: a \\
\text{real, dimension(−n1:n2)} & :: c
\end{align*}
\]

define the real array \( a \) with 11 values \( a(0) \ldots a(10) \) and the array \( c \) with 31 values \( c(-10) \ldots c(-1) \ldots c(0) \ldots c(1) \ldots c(20) \).

The arrays shown above have *dimension* 1 and they are like vectors. We can declare arrays of more than one dimension. This means that we
need more than one indices in order to determine an array element\(^4\). Therefore, the declaration

\[
\text{integer, dimension}(2,2) :: a
\]
defines an integer array with values \(a(1,1), a(1,2), a(2,1)\) and \(a(2,2)\). The following declarations define two three dimensional real arrays \(a\) and \(b\):

\[
\begin{align*}
\text{integer, parameter} & :: n1 = 10, n2 = 20, n3 = 2*n1+n2 \\
\text{real, dimension}(n1,n2,n3) & :: a \\
\text{real, dimension}(-n1:n1,0:n2,13:n3) & :: b
\end{align*}
\]

Some important definitions used in the bibliography are:

- **array**: Variables of the same type to which we refer with one or more indices. Variables with only one value are called **scalar**.

- An array’s **dimension** has an **upper bound** and a **lower bound** which define the allowed range of index values. If the lower bound is omitted in a declaration, then it takes the value 1.

- The **rank** of an array is the number of its dimensions, i.e. the number of indices needed to determine its values.

- The **extent** of a dimension it the number of its elements. It is equal to (upper bound)-(lower bound)+1.

- The **size** of an array is the total number of its elements. For a one dimensional array, its size is equal to its extent, whereas for a multi dimensional one, it is equal to the product of the extents of all of its dimensions.

- The **shape** of an array is its rank and extents of all its dimensions.

The values of arrays can be set the same way as scalars:

\[
\begin{align*}
\text{integer} & :: i \\
\text{real} & :: a(4), b(2,2) \\
b(1,1) & = 2.0 \ ; \ b(1,2) = 4.0 \\
b(2,1) & = 3.4 \ ; \ b(2,2) = 7.8
\end{align*}
\]

\(^4\)Fortran allows up to seven indices in an array.
do i=1,4
    a(i) = 1.0
enddo

Alternatively we can use the name of the array as one object:

a = (/ 1.0, 2.0, 3.0, 4.0 /)
b = 0.0

The first line defines the values of an array by using an *array constructor*. The second line defines all elements of the array b to be equal to 0. This is an example of a very convenient feature of the Fortran language. If all the arrays in an expression are *conformable*, then we can use the intrinsic Fortran operations to act on whole arrays. Two arrays are conformable if they have the same shape or if one of them is a scalar. Therefore the program

```fortran
integer :: i,j
real    :: x,y,a(10),b(10),c(4,4),d(4,4)
do  i=1,10
   a(i) = b(i)
enddo
do  j=1,4
   do i=1,4
      c(i,j) = x*d(i,j)+y
   enddo
enddo
```

is equivalent to

```fortran
integer :: i,j
real    :: x,y,a(10),b(10),c(4,4),d(4,4)
a = b
c = x*d+y
```

Many Fortran intrinsic functions are *elemental*. This means that their arguments can be arrays, in which case the function acts on each array element separately. For example, the commands

```fortran
integer :: i,j
real    :: x,y,a(10),b(10),c(4,4),d(4,4)
```
\[ c = \sin(d) + x\exp(-2.0*d) \]
\[ \text{call random_number(a)} \]

set \( c(i,j) = \sin(d(i,j)) + x\exp(-2.0*d(i,j)) \) for all \( i \) and \( j \), and the elements of \( a(i) \) equal to a random number uniformly distributed in the interval \([0, 1]\). We should stress that in order for two arrays to be conformable, it is not necessary that they have the same lower and upper bounds. For example, the command \( b = c * d \) in the following program has the same effect as the do loop:

```plaintext
integer :: i
real :: b(0:19), c(10:29), d(-9:10)

b = c*d

do i=1,20
   b(i-1) = c(i+9) * d(i-10)
enddo
```

In the following, we mention some useful functions that act on arrays. Assume that

```plaintext
real :: a(-10:10), b(-10:10), c(10:10), d(10:10), e(10:10)
```

then

- \( \text{LBOUND(a)} \) and \( \text{UBOUND(a)} \) return the lower bound and the upper bound of the array \( a \). In the above example \( \text{LBOUND(a)} = -10 \) and \( \text{UBOUND(a)} = 10 \).
- \( c = \text{TRANSPOSE(d)} \) sets \( c(i,j) = d(j,i) \).
- \( e = \text{MATMUL(c,d)} \) sets the array \( e \) equal to the matrix product \( c, d \). I.e. \( e(i,j) = \sum_{k=1}^{10} c(i,k) * d(k,j) \). Be careful, the command \( e = c * d \) sets \( e(i,j) = c(i,j) * d(i,j) \).
- \( \text{SUM(a)} \) computes the sum of all the elements of \( a \). I.e. \( \text{SUM(a)} = \sum_{i=-10}^{10} a(i) \)
- \( \text{PRODUCT(a)} \) computes the product of all the elements of \( a \). I.e. \( \text{PRODUCT(a)} = \prod_{i=-10}^{10} a(i) \)
- \( \text{DOT_PRODUCT(a,b)} \) computes the inner product of \( a, b \). I.e. \( \text{DOT_PRODUCT(a,b)} = \sum_{i=-10}^{10} a(i) * b(i) \)
1.4. THE FORTRAN PROGRAMMING LANGUAGE

- MAXVAL(a) and MINVAL(a) return the maximum and minimum values in the array a respectively.

You can find more functions and documentation in the bibliography [11,10]. In the following, we provide some information related to the Input/Output (I/O) of arrays. Input (“reading”) and output (“writing”) of array values can be done by reading and writing their elements in any order we want. In the example below, we read the array a and write the array b in two different ways:

```
integer :: i, j
real    :: a(4), b(2,2)
do i=1,4
   read *, a(i)
enddo
read *, (a(i), i=1,4)
do j=1,2
   do i=1,2
      print *, b(i,j)
   enddo
enddo
print *, (b(i,j), i=1,2), j=1,2)
```

Inside the do loops, input and output is done one element per line from/to standard input/output. The commands (a(i), i=1,4) and ( (b(i,j) i=1,2), j=1,2) are implied do loops and read/write from/to the same line. During input, if the number of values for a are exhausted, then the program tries to read values from the following line(s). Similarly, if the output of b exhausts the maximum number of characters per line, then the output continues in the next line. Try it...

We can also preform I/O of arrays without explicit reference to their elements. In this case, the arrays are read/written in a specified order. For example, the program

```
real    :: a(4), b(2,2)
read    *, a
read    *, b
```

*If we want to force a long output to be written in one line, then we must replace the * by an explicit format directive, e.g. print ' (100I6)', ( (c(i,j), i=1,10), j=1,10)
reads the values \(a(1)\ a(2)\ a(3)\ a(4)\) from the stdin. Then, it continues reading \(b(1,1),\ b(2,1),\ b(1,2),\ b(2,2)\) from the next line (record). Notice that the array \(b\) is read in a column major way. Printing \(a\) and \(b\) will print \(a(1)\ a(2)\ a(3)\ a(4)\) and \(b(1,1),\ b(2,1),\ b(1,2),\ b(2,2)\) in two different records (also in column major mode).

Finally, we summarize some of the Fortran capabilities in array manipulation. More details can be found in the bibliography. Read the comments in the program for a partial explanation of each command:

```
print *, a,b
```

```
program arrays
  implicit none

end program arrays

The code shown above can be found in the file f90_arrays.f90 of the accompanying software.

1.5 Gnuplot

Plotting data is an indispensable tool for their qualitative, but also quantitative, analysis. Gnuplot is a high quality, open source, plotting program that can be used for generating publication quality plots, as well as for heavy duty analysis of a large amount of scientific data. Its great advantage is the possibility to use it from the command line, as well as from shell scripts and other programs. Gnuplot is programmable and it is possible to call external programs in order to manipulate data and create complicated plots. There are many mathematical functions built in gnuplot and a fit command for non linear fitting of data. There exist interactive terminals where the user can transform a plot by using the mouse and keyboard commands.

This section is brief and only the features, necessary for the following chapters, are discussed. For more information visit the official page of gnuplot [http://gnuplot.info](http://gnuplot.info). Try the rich demo gallery at [http://gnuplot.info/screenshots/](http://gnuplot.info/screenshots/), where you can find the type of graph that you want to create and obtain an easy to use recipe for it. The book [14] is an excellent place to look for many of gnuplot’s secrets.³³

³³A the time of the writing of this book, there was a very nice site [www.gnuplotting.org](http://gnuplotting.org) which shows how to create many beautiful and complicated
You can start a gnuplot session with the gnuplot command:

```
> gnuplot

GNUPLOT
Version X.XX
....
The gnuplot FAQ is available from www.gnuplot.info/faq/
....
Terminal type set to 'wxt'
```

There is a welcome message and then a prompt gnuplot> is issued waiting for your command. Type a command and press [Enter]. Type quit in order to quit the program. In the following, when we show a prompt gnuplot>, it is assumed that the command after the prompt is executed from within gnuplot.

Plotting a function is extremely easy. Use the command `plot` and `x` as the independent variable of the function. The command

```
> gnuplot> plot x
```

plots the function $y = f(x) = x$ which is a straight line with slope 1. In order to plot many functions simultaneously, you can write all of them in one line:

```
> gnuplot> plot [-5:5][-2:4] x, x**2, sin(x), besj0(x)
```

The above command plots the functions $x$, $x^2$, $\sin x$ and $J_0(x)$. Within the square brackets [:], we set the limits of the $x$ and $y$ axes, respectively. The bracket $[-5:5]$ sets $-5 \leq x \leq 5$ and the bracket $[-2:4]$ sets $-2 \leq y \leq 4$. You may leave the job of setting such limits to gnuplot, by omitting some, or all of them, from the respective positions in the brackets. For example, typing `[1:]*[::5]` changes the lower and upper limits of $x$ and $y$ and leaves the upper and lower limits unchanged.

\[\text{plots.}\]

\[\text{You can change the symbol of the independent variable. For example, the command set dummy t sets the independent variable to be t.}\]

\[\text{By default, the x and y ranges are determined automatically. In order to force them to be automatic, you can insert a * in the brackets at the corresponding position(s). For example plot [1:*][*:5] sets the upper and lower limits of x and y to be determined automatically.}\]
In order to plot data points \((x_i, y_i)\), we can read their values from files. Assume that a file called `data` has the following numbers recorded in it:

```
# x  y1  y2
0.5 1.0 0.779
1.0 2.0 0.607
1.5 3.0 0.472
2.0 4.0 0.368
2.5 5.0 0.287
3.0 6.0 0.223
```

The first line is taken by gnuplot as a comment line, since it begins with a `#`. In fact, gnuplot ignores everything after a `#`. In order to plot the second column as a function of the first, type the command:

```
gnuplot> plot "data" using 1:2 with points
```

The name of the file is within double quotes. After the keyword `using`, we instruct gnuplot which columns to use as the \(x\) and \(y\) coordinates, respectively. The keywords `with points` instructs gnuplot to add each pair \((x_i, y_i)\) to the plot with points.

The command

```
gnuplot> plot "data" using 1:3 with lines
```

plots the third column as a function of the first, and the keywords `with lines` instruct gnuplot to connect each pair \((x_i, y_i)\) with a straight line segment.

We can combine several plots together in one plot:

```
gnuplot> plot "data" using 1:3 with points, \exp(-0.5*x)
gnuplot> replot "data" using 1:2
gnuplot> replot 2*x
```

The first line plots the 1st and 3rd columns in the file `data` together with the function \(e^{-x/2}\). The second line adds the plot of the 1st and 2nd columns in the file `data` and the third line adds the plot of the function \(2x\).

There are many powerful ways to use the keyword `using`. Instead of column numbers, we can put mathematical expressions enclosed inside brackets, like `using (...):(...)`. Gnuplot evaluates each expression within the brackets and plots the result. In these expressions, the values
of each column in the file data are represented as in the awk language. $i$ are variables that expand to the number read from columns $i=1,2,3,...$. Here are some examples:

```plaintext
gnuplot> plot "data" using 1:($2*sin($1)*$3) with points
gnuplot> replot 2*x*sin(x)*exp(-x/2)
```

The first line plots the 1st column of the file data together with the value $y_i \sin(x_i)z_i$, where $y_i$, $x_i$ and $z_i$ are the numbers in the 2nd, 1st and 3rd columns respectively. The second line adds the plot of the function $2x \sin(x)e^{-x/2}$.

```plaintext
gnuplot> plot "data" using (log($1)):(log($2**2))
gnuplot> replot 2*x+log(4)
```

The first line plots the logarithm of the 1st column together with the logarithm of the square of the 2nd column.

We can plot the data written to the standard output of any command. Assume that there is a program called area that prints the perimeter and area of a circle to the stdout in the form shown below:

```
> ./area
R=     3.280000    area=  33.79851
R=     6.280000    area= 123.8994
R=     5.280000    area=  87.58257
R=     4.280000    area=  57.54895
```

The interesting data is at the second and fourth columns. These can be plotted directly with the gnuplot command:

```plaintext
gnuplot> plot "< ./area" using 2:4
```

All we have to do is to type the full command after the < within the double quotes. We can create complicated filters using pipes as in the following example:

```plaintext
gnuplot> plot "< ./area | sort -g -k 2 | awk '{ print log($2),log($4)}'" using 1:2
```

The filter produces data to the stdout, by combining the action of the commands area, sort and awk. The data printed by the last program is
1.5. **GNUPLOT**

in two columns and we plot the results using 1:2.

In order to save plots in files, we have to change the `terminal` that gnuplot outputs the plots. Gnuplot can produce plots in several languages (e.g. PDF, postscript, SVG, LaTeX, jpeg, png, gif, etc), which can be interpreted and rendered by external programs. By redirecting the output to a file, we can save the plot to the hard disk. For example:

```
gnuplot> plot "data" using 1:3
```

The first line makes the plot as usual. The second one sets the output to be in the JPEG format and the third one sets the name of the file to which the plot will be saved. The fourth lines repeats all the previous plotting commands and the fifth one closes the file `data.jpg`. The last line chooses the interactive terminal `wxt` to be the output of the next plot. High quality images are usually saved in the PDF, encapsulated postscript or SVG format. Use `set terminal pdf`, `postscript eps` or `svg`, respectively.

And now a few words for 3-dimensional (3d) plotting. The next example uses the command `splot` in order to make a 3d plot of the function \( f(x, y) = e^{-x^2-y^2} \). After you make the plot, you can use the mouse in order to rotate it and view it from a different perspective:

```
gnuplot> set pm3d
```

If you have data in the form \((x_i, y_i, z_i)\) and you want to create a plot of \(z_i = f(x_i, y_i)\), write the data in a file, like in the following example:

```
-1 -1 2.000
-1  0 1.000
-1  1 2.000
0  -1 1.000
0   0 0.000
0   1 1.000
```
Note the empty line that follows the change of the value of the first column. If the name of the file is `data3`, then you can plot the data with the commands:

```
set pm3d
set hidden3d
set size ratio 1
splot "data3" with lines
```

We close this section with a few words on parametric plots. A parametric plot on the plane (2-dimensions) is a curve \((x(t), y(t))\), where \(t\) is a parameter. A parametric plot in space (3-dimensions) is a surface \((x(u,v), y(u,v), z(u,v))\), where \((u,v)\) are parameters. The following commands plot the circle \((\sin t, \cos t)\) and the sphere \((\cos u \cos v, \cos u \sin v, \sin u)\):

```
set parametric
plot \sin(t), \cos(t)
splot cos(u)*cos(v), cos(u)*sin(v), \sin(u)
```

### 1.6 Shell Scripting

Complicated system administration tasks are not among the strengths of the Fortran programming language. But in a typical GNU/Linux environment, there exist many powerful tools that can be used very effectively for this purpose. This way, one can use Fortran for the high performance and scientific computing part of the project and leave the administration and trivial data analysis tasks to other, external, programs.

One can avoid repeating the same sequence of commands by coding them in a file. An example can be found in the file `script01.csh`:

```
#!/bin/tcsh -f
gfortran area_01.f90 -o area
./area
gfortran area_02.f90 -o area
./area
```
This is a very simple shell script. The first line instructs the operating system that the lines that follow are to be interpreted by the program /bin/tcsh. This can be any program in the system, which in our case is the tcsh shell. The following lines are valid commands for the shell, one in each line. They compile the Fortran programs found in the files that we created in section 1.4 with gfortran, and then they run the executable ./area. In order to execute the commands in the file, we have to make sure that the file has the appropriate execute permissions. If not, we have to give the command:

```
> chmod u+x script01.csh
```

Then we simply type the path to the file script01.csh

```
> ./script01.csh
```

and the above commands are run the one after the other. Some of the versions of the programs that we wrote are asking for input from the stdin, which, normally, you have to type on the terminal. Instead of interacting directly with the program, we can write the input data to a file Input, and run the command

```
./area < Input
```

A more convenient solution is to use the, so called, “Here Document”. A “Here Document” is a section of the script that is treated as if it were a separate file. As such, it can be used as input to programs by sending its “contents” to the stdin of the command that runs the program. The “Here Document” does not appear in the filesystem and we don’t need to administer it as a regular file. An example of using a “Here Document” can be found in the file script02.csh:

```
#!/bin/tcsh
```

---

**Footnotes:***

66Use #!/bin/bash if you prefer the bash shell.

67Their great advantage is that we can use variable and command substitution in them, therefore sending this information to the program that we want to run.
CHAPTER 1. THE COMPUTER

```
gfortran area_04.f90 –o area
./area <<EOF
1.0
2.0
3.0
4.0
5.0
6.0
7.0
8.0
9.0
10.0
EOF
```

The stdin of the command ./area is redirected to the contents between the lines

```
./area <<EOF
...
EOF
```

The string EOF marks the beginning and the end of the “Here Document”, and can be any string you like. The last EOF has to be placed exactly in the beginning of the line.

The power of shell scripting lies in its programming capabilities: Variables, arrays, loops and conditionals can be used in order to create a complicated program. Shell variables can be used as discussed in section 1.1.2. The value of a variable name is $name and it can be set with the command set name = value. An array is defined, for example, by the command

```
set R = (1.0 2.0 3.0 4.0 5.0 6.0 7.0 8.0 9.0 10.0)
```

and its data can be accessed using the syntax $R[1] ... $R[10].

Let’s take a look at the following script:

```
#!/bin/tcsh –f
set files = (area_01.f90 area_02.f90 area_03.f90 area_04.f90)
set R = (1.0 2.0 3.0 4.0 5.0 6.0 7.0 8.0 9.0 10.0)
echo "Hello $USER Today is " 'date'
foreach file (files)
  echo "# ---------------- Working on file $file "
```

The first two lines of the script define the values of the arrays files (4 values) and R (10 values). The command echo echoes its argument to the stdin. $USER is the name of the user running the script. `date` is an example of command substitution: When a command is enclosed between backquotes and is part of a string, then the command is executed and its stdout is pasted back to the string. In the example shown above, `date` is replaced by the current date and time in the format produced by the date command.

The foreach loop

```bash
foreach file ($files)
    ...
end
```

is executed once for each of the 4 values of the array files. Each time the value of the variable file is set equal to one of the values area_01.f90, area_02.f90, area_03.f90, area_04.f90. These values can be used by the commands in the loop. Therefore, the command gfortran $file -o area compiles a different file each time that it is executed by the loop.

The last line in the loop

```bash
if( -f AREA.DAT ) cat AREA.DAT
```

is a conditional. It executes the command cat AREA.DAT if the condition -f AREA.DAT is true. In this case, -f constructs a logical expression which is true when the file AREA.DAT exists.

We close this section by presenting a more complicated and advanced
script. It only serves as a demonstration of the shell scripting capabilities. For more information, the reader is referred to the bibliography \[16,17,18,19,20\]. Read carefully the commands, as well as the comments which follow the # mark. Then, write the commands to a file script04.csh make it an executable file with the command chmod u+x script04.csh and give the command

```
> ./script04.csh This is my first serious tcsh script
```

The script will run with the words “This is my first serious tcsh script” as its arguments. Notice how these arguments are manipulated by the script. Then, the script asks for the values of the radii of ten or more circles interactively, so that it will compute their perimeter and area. Type them on the terminal and then observe the script’s output, so that you understand the function of each command. You will not regret the time investment!

```bash
#!/bin/tcsh
# Run this script as:
# . /script04.csh Hello this is a tcsh script
#
# 'command' is command substitution: it is replaced by stdout of command
set now = `date` ; set mypc = `uname -a`
# Print information: variables are expanded within double quotes
echo "I am user $user working on the computer $HOST" #HOST is predefined
echo "Today the date is : $now" #now is defined above
echo "My home directory is : $home" #home is predefined
echo "My current directory is: $cwd" #cwd changes with cd
echo "My computer runs : $mypc" #mypc is defined above
echo "My process id is : $$" #$$ is predefined
# Manipulate the command line: ($#argv is number of elements in array argv)

echo "The command line has $#argv arguments"

echo "The name of the command I am running is: $0"

echo "Arguments 3rd to last of the command : $argv[3-]" #third to last

echo "The last argument is : $argv[ $#argv ]" #last element

echo "All arguments : $argv"

# Ask user for input: enter radii of circles

echo -n "Enter radii of circles: " # variable $< stores one line of input

set Rs = ($<) # Rs is now an array with all words entered by user
if ($#Rs < 10 ) then # make a test, need at least 10 of them
  echo "Need more than 10 radii. Exiting...."
  exit(1)
endif

echo "You entered $#Rs radii. the first is $Rs[1] and the last $Rs[$#Rs]"

echo " Rs= $Rs"
# Now, compute the perimeter of each circle:

define Rs
# -v rad=5R set the awk variable rad equal to $R, pi=atan2(0,-1)=3.14...
set 1 = `awk -v rad=$R 'BEGIN{print 2*atan2(0,-1)*rad)'
```

\[48\] You will find it also in the accompanying software
echo "Circle with $\text{R} = \text{SR}$ has perimeter $\pi $"
end
# alias defines a command to do what you want: use awk as a calculator
alias acalc 'awk "BEGIN{ print \! ^! }"' # \! ^! substitutes args of acalc
echo "Using acalc to compute $2+3$" "acalc 2+3"
echo "Using acalc to compute $\cos(2\pi)" = "acalc $\cos(2\ast\text{atan2}(0,-1))$" # Now do the same loop over radii as above in a different way
# while( expression ) is executed as long as "expression" is true
while($\#Rs > 0) # executed as long as $\$Rs$ contains radii
set R = $Rs[1]$ # take first element of $Rs
shift Rs # now $Rs$ has one less element: old $Rs[1]$ has vanished
set a = 'acalc $\text{atan2}(0,-1)\ast\text{\$Rs[1]}\ast\text{\$Rs[1]}$' # = $\pi \ast R$ calculated by acalc
# construct a filename to save the result from the value of R:
set file = area$\{R\}.dat
echo "Circle with $\text{R} = \text{SR}$ has area $\%s$" > $file #save result in a file
end # end while
# Now look for our files: save their names in an array files:
set files = ('$ls -$l area*.dat')
if( $#files == 0) echo "Sorry, no area files found"

# calculate all the! negatives the expression (true -> false, false -> true)
set f = $files[1]$ # test permissions on first file
# -f, -r, -w, -x, -d test existence of file, rwxd permissions
# the ! negates the expression (true -> false, false -> true)
echo "testing permissions on files:"
if( $f ) echo "$f$ exists"
if( ! -f $f ) echo "$f$ is readable by me"
if( ! -w $f ) echo "$f$ is writable by be"
if( ! -x $f ) echo "$f$ is NOT executable"
if( ! -x $f ) echo "$f$ is NOT executable by me"
if( ! -d $f ) echo "$f$ is NOT a directory"
if( ! -d $f ) echo "$f$ is a directory"

# transform the name of a file
set f = $cwd/$f # add the full path in $f
set filename = $f:r # removes extension .dat
set extension = $f:e # gets extension .dat
set fdir = $f:h # gets directory of $f
set base = "basename $f" # removes directory name
echo "file is: $f"
echo "filename is: $filename"
echo "extension is: $extension"
echo "directory is: $fdir"
echo "basename is: $base"
# now transform the name to one with different extension:
set newfile = $[filename].jpg
echo "jpeg name is: $newfile"
echo "jpeg base is:" 'basename $newfile'
if($newfile:e == jpg)echo 'basename $newfile'" is a picture"
echo "" # Now save all data in a file using a "here document"
# A here document starts with <<EOF and ends with a line
# starting exactly with EOF (EOF can be any string as below)
# In a "here document" we can use variables and command
# substitution:

```bash
cat <<<AREAS >> areas.dat
```

# This file contains the areas of circle of given radii
# Computation done by ${user} on ${HOST}. Today is ‘date’

'cat $files'

AREAS

# now see what we got:

```bash
if( !-f areas.dat) cat areas.dat
```

# You can use a "here document" as standard input to any command:
# use gnuplot to save a plot: gnuplot does the job and exits...

```bash
gnuplot <<<GNU
set terminal jpeg
set output "areas.jpg"
plot "areas.dat" using 4:7 title "areas.dat",\ 
    pi*x*x title "pi*R^2"
set output
GNU
```

# check our results: display the jpeg file using eog

```bash
if( !-f areas.jpg) eog areas.jpg &
```

```bash
```
Figure 1.5: In this figure, the Emacs window has been split in three windows. The splitting was done horizontally first (C-x 2), and then vertically (C-x 3). By dragging the mouse (Drag-Mouse-1) on the horizontal mode lines and vertical lines that separate the windows, we can change window sizes. Notice the useful information displayed on the mode lines. Each window has one point and the cursor is on the active window (in this case the window of the buffer named ELines.f). A buffer with no active changes in its content is marked by a --, an edited buffer is marked by ** and a buffer in read-only mode with (%%). With a mouse click on a %, we can change them to -- (so that we can edit) and vice versa. With Mouse-3 on the name of a mode we can activate a choice of minor modes. With Mouse-1 on the name of a mode we can have access to commands relevant to the mode. The numbers (17,31), (16,6) and (10,15) on the mode lines show the (line,column) of the point location on the respective windows.

Chapter 2

Kinematics

In this chapter we show how to program simple kinematic equations of motion of a particle and how to do basic analysis of numerical results. We use simple methods for plotting and animating trajectories on the two dimensional plane and three dimensional space. In section 2.3 we study numerical errors in the calculation of trajectories of freely moving particles bouncing off hard walls and obstacles. This will be a prelude to the study of the integration of the dynamical equations of motion that we will introduce in the following chapters.

2.1 Motion on the Plane

When a particle moves on the plane, its position can be given in Cartesian coordinates \((x(t), y(t))\). These, as a function of time, describe the particle’s trajectory. The position vector is \(\vec{r}(t) = x(t) \hat{x} + y(t) \hat{y}\), where \(\hat{x}\) and \(\hat{y}\) are the unit vectors on the \(x\) and \(y\) axes respectively. The velocity vector is \(\vec{v}(t) = v_x(t) \hat{x} + v_y(t) \hat{y}\) where

\[
\vec{v}(t) = \frac{d\vec{r}(t)}{dt}, \quad v_x(t) = \frac{dx(t)}{dt}, \quad v_y(t) = \frac{dy(t)}{dt},
\]

(2.1)

The acceleration \(\vec{a}(t) = a_x(t) \hat{x} + a_y(t) \hat{y}\) is given by

\[
\vec{a}(t) = \frac{d\vec{v}(t)}{dt} = \frac{d^2\vec{r}(t)}{dt^2}, \quad a_x(t) = \frac{dv_x(t)}{dt} = \frac{d^2x(t)}{dt^2}, \quad a_y(t) = \frac{dv_y(t)}{dt} = \frac{d^2y(t)}{dt^2}.
\]

(2.2)
CHAPTER 2. KINEMATICS

Figure 2.1: The trajectory of a particle moving in the plane. The figure shows its position vector \( \vec{r} \), velocity \( \vec{v} \) and acceleration \( \vec{a} \) and their Cartesian components in the chosen coordinate system at a point of the trajectory.

In this section we study the kinematics of a particle trajectory, therefore we assume that the functions \((x(t), y(t))\) are known. By taking their derivatives, we can compute the velocity and the acceleration of the particle in motion. We will write simple programs that compute the values of these functions in a time interval \([t_0, t_f]\), where \(t_0\) is the initial and \(t_f\) is the final time. The continuous functions \(x(t), y(t), v_x(t), v_y(t)\) are approximated by a discrete sequence of their values at the times \(t_0, t_0 + \delta t, t_0 + 2\delta t, t_0 + 3\delta t, \ldots\) such that \(t_0 + n\delta t \leq t_f\).

We will start the design of our program by forming a generic template to be used in all of the problems of interest. Then we can study each problem of particle motion by programming only the equations of motion without worrying about the less important tasks, like input/output, user interface etc. Figure 2.2 shows a flowchart of the basic steps in the algorithm. The first part of the program declares variables and defines the values of the fixed parameters (like \(\pi = 3.1459\ldots\), \(g = 9.81\), etc). The program starts by interacting with the user (“user interface”) and asks for the values of the variables \(x_0, y_0, t_0, t_f, \delta t\ldots\). The program prints these values to the stdout so that the user can check them for correctness and store them in her data.

The main calculation is performed in a loop executed while \(t \leq t_f\). The values of the positions and the velocities \(x(t), y(t), v_x(t), v_y(t)\) are
2.1. MOTION ON THE PLANE

Figure 2.2: The flowchart of a typical program computing the trajectory of a particle from its (kinematic) equations of motion.

Calculated and printed in a file together with the time \( t \). At this point we fix the format of the program output, something that is very important to do it in a consistent and convenient way for easing data analysis. We choose to print the values \( t, x, y, vx, vy \) in five columns in each line of the output file.

The specific problem that we are going to solve is the computation of the trajectory of the circular motion of a particle on a circle with center \((x_0, y_0)\) and radius \( R \) with constant angular velocity \( \omega \). The position on the circle can be defined by the angle \( \theta \), as can be seen in figure 2.3. We define the initial position of the particle at time \( t_0 \) to be \( \theta(t_0) = 0 \).

The equations giving the position of the particle at time \( t \) are

\[
\begin{align*}
x(t) &= x_0 + R \cos \left( \omega(t - t_0) \right) \\
y(t) &= y_0 + R \sin \left( \omega(t - t_0) \right).
\end{align*}
\]

(2.3)

Taking the derivative w.r.t. \( t \) we obtain the velocity

\[
\begin{align*}
v_x(t) &= -\omega R \sin \left( \omega(t - t_0) \right) \\
v_y(t) &= \omega R \cos \left( \omega(t - t_0) \right).
\end{align*}
\]

(2.4)
CHAPTER 2. KINEMATICS

Figure 2.3: The trajectory of a particle moving on a circle with constant angular velocity calculated by the program Circle.f90.

and the acceleration

\[ a_x(t) = -\omega^2 R \cos (\omega(t - t_0)) = -\omega^2(x(t) - x_0) \]
\[ a_y(t) = -\omega^2 R \sin (\omega(t - t_0)) = -\omega^2(y(t) - y_0). \]  

(2.5)

We note that the above equations imply that \( \vec{R} \cdot \vec{v} = 0 \) (\( \vec{R} \equiv \vec{r} - \vec{r}_0, \vec{v} \perp \vec{R} \)), \( \vec{v} \) tangent to the trajectory) and \( \vec{a} = -\omega^2 \vec{R} \) (\( \vec{R} \) and \( \vec{a} \) anti-parallel, \( \vec{a} \perp \vec{v} \)).

The data structure is quite simple. The constant angular velocity \( \omega \) is stored in the REAL variable \( \omega \). The center of the circle \((x_0,y_0)\), the radius \( R \) of the circle and the angle \( \theta \) are stored in the REAL variables \( x_0, y_0, R, \theta \). The times at which we calculate the particle’s position and velocity are defined by the parameters \( t_0, t_f, \delta t \) and are stored in the REAL variables \( t_0, t_f, \delta t \). The current position \((x(t),y(t))\) is calculated and stored in the REAL variables \( x, y \) and the velocity \((v_x(t),v_y(t))\) in the REAL variables \( v_x, v_y \). The declarations of the variables are put in the beginning of the program:

\[
\begin{align*}
\text{real} &::= x0,y0,R,x,y,vx,vy,t,t0,tf,dt \\
\text{real} &::= \theta,\omega \\
\text{real, parameter} &::= \text{PI}=3.1415927
\end{align*}
\]

were we defined the value\(^{1}\) of \( \pi = 3.1415927 \) by using the parameter specification.

\(^{1}\)The reader is reminded that REAL variables are stored in 4 bytes and have an accuracy of about 7 decimal digits.
The user interface of the program is the interaction of the program with the user and, in our case, it is the part of the program where the user enters the parameters \( \omega, x_0, y_0, R, t_0, t_f, \Delta t \). The program issues a prompt with the names the variables expected to be read. This is done using simple print statements. The variables are read from the stdin by simple read statements and the values entered by the user are printed to the stdout²:

```plaintext
print *, '# Enter omega:'
read *, \omega
print *, '# Enter center of circle (x0,y0) and radius R:'
read *, x0, y0, R
print *, '# Enter t0, t_f, \Delta t:'
read *, t0, tf, \Delta t
print *, '# omega= ', \omega
print *, '# x0= ', x0, ' y0= ', y0, ' R= ', R
print *, '# t0= ', t0, ' t_f= ', tf, ' \Delta t= ', \Delta t
```

Next, the program initializes the state of the computation. This includes checking the validity of the parameters entered by the user, so that the computation will be possible. For example, the program computes the expression \( 2.0*\pi/\omega \), where it is assumed that \( \omega \) has a non-zero value. We will also demand that \( R > 0 \) and \( \omega > 0 \). An if statement will make those checks and if the parameters have illegal values, the stop statement will stop the program execution³. The program opens the file Circle.dat for writing the calculated values of the position and the velocity of the particle.

```plaintext
if (R .le. 0.0) stop 'Illegal value of R'
if (omega .le. 0.0) stop 'Illegal value of omega'
print *, '# T= ', 2.0*\pi/omega
open(unit=11, file='Circle.dat')
```

If \( R \leq 0 \) or \( \omega \leq 0 \) the corresponding stop statements are executed which end the program execution. The optional error messages are included after the stop statements which are printed to the stdout. The value of the period \( T = 2\pi/\omega \) is also calculated and printed for reference.

The open statement uses unit 11 for writing to the file Circle.dat.

²This is done so that the user can check for typos and see the actual value read by the program. By redirecting the stdout of a file on the hard disk, the parameters can be saved for future reference and used in data analysis.
³Note that there are more assumptions that need to be checked by the program. We leave this as an exercise for the reader.
The choice of the unit number is free for the programmer to choose. We recommend using the units 10 to 99 for input/output to files\footnote{Some numbers can be reserved for special files, like 5 for stdin, 6 for stdout and 0 for stderr. Using numbers larger than 99 can lead to portability problems.}.

The main calculation is performed within the loop

\[
\begin{align*}
t &= t_0 \\
do\ while&(t \leq t_f) \\
& \quad \ldots . \ldots . \\
&t = t + dt \\
enddo
\end{align*}
\]

The first statement sets the initial value of the time. The statements between the do while\((\text{condition})\) and enddo are executed as long as \text{condition} has a .TRUE. value. The statement \(t=t+dt\) increments the time and this is necessary in order not to enter into an infinite loop. The commands put in place of the dots \ldots .\ldots . calculate the position and the velocity and print them to the file Circle.dat:

\[
\begin{align*}
\theta &= \omega \ast (t-t_0) \\
x &= x_0+R\ast \cos(\theta) \\
y &= y_0+R\ast \sin(\theta) \\
v_x &= -\omega R \ast \sin(\theta) \\
v_y &= \omega R \ast \cos(\theta) \\
\text{write}(11,*&)t,x,y,vx,vy
\end{align*}
\]

Notice the use of the intrinsic functions \(\sin\) and \(\cos\) that calculate the sine and cosine of an angle expressed in radians. We use the intermediate variable \(\theta\) in order to store the phase \(\theta(t) = \omega(t-t_0)\). The command \text{write}(11,*&) writes the variables \(t,x,y,vx,vy\) to the unit 11, which has been associated to the file Circle.dat with the open statement shown above.

The program is stored in the file Circle.f90 and can be found in the accompanied software. The extension .f90 is used by the compiler in order to denote source code written in free format Fortran language. Compilation and running can be done using the commands:

\[
\begin{align*}
> & \text{gfortran} \ Circle.f90 \ -o \ cl \\
> & ./cl
\end{align*}
\]

The switch \(-o \ cl\) forces the compiler gfortran to write the binary com-
mands executed by the program to the file c1. The command ./c1 loads the program instructions to the computer memory for execution. When the programs starts execution, it first asks for the parameter data and then performs the calculation. A typical session looks like:

```
> gfortran Circle.f90 -o c1
> ./c1
  # Enter omega:
  1.0
  # Enter center of circle (x0,y0) and radius R:
  1.0 1.0 0.5
  # Enter t0,tf,dt:
  0.0 20.0 0.01
  # omega= 1.
  # x0= 1.0 y0= 1.0 R= 0.5
  # t0= 0.0 tf= 20.0 dt= 0.00999999978
  # T= 6.28318548
```

The lines shown above that start with a # character are printed by the program and lines without # are the values of the parameters entered interactively by the user. The user types in the parameters and then presses the Enter key in order for the program to read them. Here we have $\omega = 1.0$, $x_0 = y_0 = 1.0$, $R = 0.5$, $t_0 = 0.0$, $t_f = 20.0$ and $\Delta t = 0.01$.

You can execute the above program many times for different values of the parameter by writing the parameter values in a file using an editor. For example, in the file Circle.in type the following data:

```
1.0 omega
1.0 1.0 0.5 (x0, y0), R
0.0 20.0 0.01 t0 tf dt
```

Each line has the parameters read by the program with a read statement (a record). The rest of the line is ignored by the program and the user can write anything she likes as a comment on how to use the parameters. The program can read the above values of the parameters with the command:

```
> ./c1 < Circle.in > Circle.out
```

The command ./c1 runs the commands found in the executable file ./c1. The < Circle.in redirects the contents of the file Circle.in to the standard input (stdin) of the command ./c1. This way the program reads

---

If omitted, the executable file has the default name a.out.
in the values of the parameters from the contents of the file Circle.in. The > Circle.out redirects the standard output (stdout) of the command ./cl to the file Circle.out. Its contents can be inspected after the execution of the program with the command cat:

```bash
> cat Circle.out
# Enter omega:
# Enter center of circle (x0,y0) and radius R:
# Enter t0, tf, dt:
# omega=  1.
# x0=  1. y0=  1. R=  0.5
# t0=  0. tf=  20. dt=  0.00999999978
# T=  6.28318548
```

We list the full program in Circle.f90 below:

```fortran
!============================================================================
!File  Circle.f90

```

2.1. MOTION ON THE PLANE

Compute:
\[ t = t_0 \]
do while (t .le. tf)
    \[ \theta = \omega \cdot (t - t_0) \]
    \[ x = x_0 + R \cdot \cos(\theta) \]
    \[ y = y_0 + R \cdot \sin(\theta) \]
    \[ vx = -\omega \cdot R \cdot \sin(\theta) \]
    \[ vy = \omega \cdot R \cdot \cos(\theta) \]
    write (11,*), t, x, y, vx, vy
    t = t + dt
endo
close(11)
end program Circle

2.1.1 Plotting Data

We use gnuplot for plotting the data produced by our programs. The file Circle.dat has the time \( t \) and the components \( x, y, vx, vy \) in five columns. Therefore we can plot the functions \( x(t) \) and \( y(t) \) by using the gnuplot commands:

```
plot "Circle.dat" using 1:2 with lines title "x(t)"
replot "Circle.dat" using 1:3 with lines title "y(t)"
```

Figure 2.4: The plots \( (x(t), y(t)) \) (left) and \( \theta(t) \) (right) from the data in Circle.dat for \( \omega = 1.0, x_0 = y_0 = 1.0, R = 0.5, t_0 = 0.0, t_f = 20.0 \) and \( \delta t = 0.01 \).

The second line puts the second plot together with the first one. The results can be seen in figure 2.4.

Let’s see now how we can make the plot of the function \( \theta(t) \). We can do that using the raw data from the file Circle.dat within gnuplot, without having to write a new program. Note that \( \theta(t) = \tan^{-1} \left( \frac{y - y_0}{x - x_0} \right) \).
The function \( \text{atan2} \) is available in gnuplot as well as in Fortran. Use the online help system in gnuplot in order to see its usage:

\[
\text{gnuplot}> \text{help atan2}
\]

The \( \text{atan2}(y,x) \) function returns the arc tangent (inverse tangent) of the ratio of the real parts of its arguments. \( \text{atan2} \) returns its argument in radians or degrees, as selected by \( \text{set angles} \), in the correct quadrant.

Therefore, the right way to call the function is \( \text{atan2}(y-y_0,x-x_0) \). In our case \( x_0=y_0=1 \) and \( x, y \) are in the 2nd and 3rd columns of the file \( \text{Circle.dat} \). We can construct an expression after the using command as in page 30, where \( \$2 \) is the value of the second and \( \$3 \) the value of the third column:

\[
\text{gnuplot}> x_0 = 1 ; \ y_0 = 1
\]

\[
\text{gnuplot}> \text{plot } "\text{Circle.dat}" \text{ using } 1:(\text{atan2}($3-y0,$2-x0)) \ \ \\
\text{with lines title } "\theta(t)\" \text{, pi,-pi}
\]

The second command is broken in two lines by using the character \( \backslash \) so that it fits conveniently in the text. Note how we defined the values of the variables \( x_0, y_0 \) and how we used them in the expression \( \text{atan2}($3-x0,$2-y0) \). We also plot the lines which graph the constant functions \( f_1(t) = \pi \) and \( f_2(t) = -\pi \) which mark the limit values of \( \theta(t) \). The gnuplot variable \( \pi \) is predefined and can be used in formed expressions. The result can be seen in the left plot of figure 2.4.

The velocity components \( (v_x(t), v_y(t)) \) as function of time as well as the trajectory \( \vec{r}(t) \) can be plotted with the commands:

\[
\text{gnuplot}> \text{plot } "\text{Circle.dat}" \text{ using } 1:4 \text{ title } "v_x(t)" \ \ \\
\text{with lines}
\]

\[
\text{gnuplot}> \text{replot } "\text{Circle.dat}" \text{ using } 1:5 \text{ title } "v_y(t)" \ \ \\
\text{with lines}
\]

\[
\text{gnuplot}> \text{plot } "\text{Circle.dat}" \text{ using } 2:3 \text{ title } "x-y" \ \ \\
\text{with lines}
\]

We close this section by showing how to do a simple animation of the particle trajectory using gnuplot. There is a file animate2D.gnu in the accompanied software which you can copy in the directory where you

---

6 The command \( \text{help functions} \) will show you all the available functions in gnuplot.

7 This can be done on the gnuplot command line as well.

8 Use the command \( \text{show variables} \) in order to see the current/default values of gnuplot variables.
2.1. MOTION ON THE PLANE

Figure 2.5: The particle trajectory plotted by the gnuplot program in the file animate2D.gnu of the accompanied software. The position vector is shown at a given time \( t \), which is marked on the title of the plot together with the coordinates \((x,y)\). The data is produced by the program Circle.f90 described in the text.

have the data file Circle.dat. We are not going to explain how it works, but how to use it in order to make your own animations. The final result is shown in figure 2.5. All that you need to do is to define the data file\(^9\) the initial time \( t_0 \), the final time \( t_f \) and the time step \( dt \). These times can be different from the ones we used to create the data in Circle.dat. A full animation session can be launched using the commands:

```
file = "Circle.dat"
set xrange \[0:1.6\]; set yrange \[0:1.6\]
t0 = 0; tf = 20; dt = 0.1
load "animate2D.gnu"
```

The first line defines the data file that animate2D.gnu reads data from. The second line sets the range of the plots and the third line defines the time parameters used in the animation. The final line launches the animation. If you want to rerun the animation, you can repeat the last two commands as many times as you want using the same or different parameters. E.g. if you wish to run the animation at “half the speed”\(^9\)

\(^9\)You are most welcome to study the commands in the script and guess how it works of course!

\(^9\)It can be any file that has \((t,x,y)\) in the 1st, 2nd and 3rd columns respectively.
you should simply redefine $dt=0.05$ and set the initial time to $t_0=0$:

\begin{verbatim}
$gnuplot$ t0 = 0; dt = 0.05
$gnuplot$ load "animate2D.gnu"
\end{verbatim}

### 2.1.2 More Examples

We are now going to apply the steps described in the previous section to other examples of motion on the plane. The first problem that we are going to discuss is that of the small oscillations of a simple pendulum. Figure 2.6 shows the single oscillating degree of freedom $\theta(t)$, which is the small angle that the pendulum forms with the vertical direction. The motion is periodic with angular frequency $\omega = \sqrt{g/l}$ and period $T = 2\pi/\omega$. The angular velocity is computed from $\dot{\theta} \equiv d\theta/dt$ which gives

\begin{align}
\theta(t) &= \theta_0 \cos \left( \omega \left( t - t_0 \right) \right) \\
\dot{\theta}(t) &= -\omega \theta_0 \sin \left( \omega \left( t - t_0 \right) \right)
\end{align}

Figure 2.6: The simple pendulum whose motion for $\theta \ll 1$ is described by the program SimplePendulum.f90.

We have chosen the initial conditions $\theta(t_0) = \theta_0$ and $\dot{\theta}(t_0) = 0$. In order to write the equations of motion in the Cartesian coordinate system shown in figure 2.6 we use the relations

\begin{align}
x(t) &= l \sin \left( \theta(t) \right) \\
y(t) &= -l \cos \left( \theta(t) \right) \\
v_x(t) &= \frac{dx(t)}{dt} = l\dot{\theta}(t) \cos \left( \theta(t) \right) \\
v_y(t) &= \frac{dy(t)}{dt} = l\dot{\theta}(t) \sin \left( \theta(t) \right).
\end{align}
These are similar to the equations \((2.3)\) and \((2.4)\) that we used in the case of the circular motion of the previous section. Therefore the structure of the program is quite similar. Its final form, which can be found in the file SimplePendulum.f90, is:

```fortran
!====================================================================
! File SimplePendulum.f90
! Set pendulum original position at theta0 with no initial speed
!
program SimplePendulum
   implicit none
!
! Declaration of variables
   real :: l, x, y, vx, vy, t, t0, tf, dt
   real :: theta, theta0, dtheta_dt, omega
   real, parameter :: PI=3.1415927, g=9.81
!
! Ask user for input:
   print *, '# Enter l: ', read *, l
   print *, '# Enter theta0: ', read *, theta0
   print *, '# Enter t0, tf, dt: ', read *, t0, tf, dt
   print *, '# l= ', l, ', theta0= ', theta0
   print *, '# t0= ', t0, ', tf= ', tf, ', dt= ', dt
!
! Initialize
   omega = sqrt(g/l)
   print *, '# omega= ', omega, ', T= ', 2.0*PI/omega
   open(unit=11, file='SimplePendulum.dat')
!
! Compute:
   t = t0
   do while(t .le. tf)
      theta = theta0*cos(omega*(t-t0))
      dtheta_dt = -omega*theta0*sin(omega*(t-t0))
      x = l*sin(theta)
      y = -l*cos(theta)
      vx = l*dtheta_dt*cos(theta)
      vy = l*dtheta_dt*sin(theta)
      write(11,100) t, x, y, vx, vy, theta, dtheta_dt
      t = t + dt
   enddo
   close(11)
100 FORMAT(7G15.7)
end program SimplePendulum
```
We note that the acceleration of gravity $g$ is hard coded in the program and that the user can only set the length $l$ of the pendulum. The data file SimplePendulum.dat produced by the program, contains two extra columns with the current values of $\theta(t)$ and the angular velocity $\dot{\theta}(t)$. The statement `write(11,100)` writes to the unit 11 according to the format set by the `FORMAT` statement, found in the line labeled by the label 100. This is done so that we can be sure that the data is printed in one line for each value of $t$ (see the discussion on page\[48\]).

A simple session for the study of the above problem is shown below:\[¹¹\]:

```plaintext
> gfortran SimplePendulum.f90 -o sp
> ./sp
  # Enter l:
  1.0
  # Enter theta0:
  0.314
  # Enter t0,tf,dt:
  0 20 0.01
  # l= 1. theta0= 0.31400001
  # t0= 0. tf= 20. dt= 0.0099999978
  # omega= 3.132092 T= 2.0060668
> gnuplot
  gnuplot> plot "SimplePendulum.dat" u 1:2 w l t "x(t)"
  gnuplot> plot "SimplePendulum.dat" u 1:3 w l t "y(t)"
  gnuplot> replot "SimplePendulum.dat" u 1:4 w l t "v_x(t)"
  gnuplot> plot "SimplePendulum.dat" u 1:5 w l t "v_y(t)"
  gnuplot> replot "SimplePendulum.dat" u 1:6 w l t "theta(t)"
  gnuplot> replot "SimplePendulum.dat" u 1:7 w l t "theta'(t)"
  gnuplot> plot [-0.6:0.6][-1.1:0.1] "SimplePendulum.dat" u 2:3 w l t "x-y"
  gnuplot> file = "SimplePendulum.dat"
  gnuplot> t0=0;tf=20.0;dt=0.1
  gnuplot> set xrange [-0.6:0.6]; set yrange [-1.1:0.1]
  gnuplot> load "animate2D.gnu"
```

The next example is the study of the trajectory of a particle shot near the earth’s surface\[¹²\] when we consider the effect of air resistance to be negligible. Then, the equations describing the trajectory of the particle

\[¹¹\] Notice that we replaced the command “using 1:2 with lines title” with “u 1:2 w l t "x(t)"”. These abbreviations can be done with every gnuplot command if an abbreviation uniquely determines a command.

\[¹²\] I.e. $\vec{g}$ = const. and the Coriolis force can be ignored.
2.1. MOTION ON THE PLANE

and its velocity are given by the parametric equations

\[
\begin{align*}
x(t) &= v_0x t \\
y(t) &= v_0y - \frac{1}{2} gt^2 \\
v_x(t) &= v_0x \\
v_y(t) &= v_0y - gt,
\end{align*}
\]

where \( t \) is the parameter. The initial conditions are \( x(0) = y(0) = 0 \), \( v_x(0) = v_0x = v_0 \cos \theta \) and \( v_y(0) = v_0y = v_0 \sin \theta \), as shown in figure 2.7.

![Figure 2.7: The trajectory of a particle moving under the influence of a constant gravitational field. The initial conditions are set to \( x(0) = y(0) = 0 \), \( v_x(0) = v_0x = v_0 \cos \theta \) and \( v_y(0) = v_0y = v_0 \sin \theta \).](image)

The structure of the program is similar to the previous ones. The user enters the magnitude of the particle’s initial velocity and the shooting angle \( \theta \) in degrees. The initial time is taken to be \( t_0 = 0 \). The program calculates \( v_{0x} \) and \( v_{0y} \) and prints them to the stdout. The data is written to the file Projectile.dat. The full program is listed below and it can be found in the file Projectile.f90 in the accompanied software:

```fortran
program Projectile
  implicit none

! Declaration of variables
  real :: x0,y0,R,x,y,vx,vy,t,tf,dt
```

---

*File Projectile.f90*

*Shooting a projectile near the earth surface.*

*No air resistance.*

*Starts at (0,0), set (v0,theta).*

---

2.1. MOTION ON THE PLANE

Next, we will study the effect of air resistance of the form $\vec{F} = -mk\vec{v}$. The solutions to the equations of motion

$$
\begin{align*}
    a_x &= \frac{dv_x}{dt} = -kv_x \\
    a_y &= \frac{dv_y}{dt} = -kv_y - g
\end{align*}
$$

(2.9)

with initial conditions $x(0) = y(0) = 0$, $v_x(0) = v_{0x} = v_0 \cos \theta$ and $v_y(0) = v_{0y} = v_0 \sin \theta$ are

$$
\begin{align*}
    v_x(t) &= v_{0x} e^{-kt} \\
    v_y(t) &= (v_{0y} + \frac{g}{k}) e^{-kt} - \frac{g}{k} \\
    x(t) &= \frac{v_{0x}}{k} (1 - e^{-kt}) \\
    y(t) &= \frac{1}{k} \left( v_{0y} + \frac{g}{k} \right) (1 - e^{-kt}) - \frac{g}{k} t
\end{align*}
$$

(2.10)

Programming the above equations is as easy as before, the only difference being that the user needs to provide the value of the constant $k$.

The proof of equations (2.10) is left as an exercise for the reader.
CHAPTER 2. KINEMATICS

The full program can be found in the file ProjectileAirResistance.f90 and it is listed below:

```fortran
! File ProjectileAirResistance.f90

    vx = v0x*exp(-k*t)
    vy = (v0y+(g/k))*exp(-k*t)-(g/k)
    write(11,*), t, x, y, vx, vy
    t = t + dt
  enddo
  close(11)
```
2.1. MOTION ON THE PLANE

end program ProjectileAirResistance

Figure 2.9: The plots of \( x(t), y(t) \) (left) and \( v_x(t), v_y(t) \) (right) from the data produced by the program ProjectileAirResistance.f90 for \( k = 5.0, v_0 = 10.0, \theta = \pi/4, t_f = 0.91 \) and \( \Delta t = 0.001 \). We also plot the asymptotes of these functions as \( t \to \infty \).

We also list the commands of a typical session of the study of the problem:

```bash
> gfortran ProjectileAirResistance.f90 -o pja
> ./pja
  # Enter k, v0, theta (in degrees):
  5.0 10.0 45
  # Enter tf, dt:
  0.91 0.001
  # k = 5.
  # v0 = 10. theta = 45.0 (degrees)
  # t0 = 0, tf = 0.910000026 dt = 0.00100000005
  # v0x = 7.07106781 v0y = 7.07106781
> gnuplot
  gnuplot> v0x = 10*cos(pi/4); v0y = 10*sin(pi/4)
  gnuplot> g = 9.81; k = 5
  gnuplot> plot [:][:v0x/k+0.1] "ProjectileAirResistance.dat" \using 1:2 with lines title "x(t)",v0x/k
  gnuplot> replot "ProjectileAirResistance.dat" \using 1:3 with lines title "y(t)",\-(g/k)*x+(g/k**2)+v0y/k
  gnuplot> plot [:][-g/k-0.6:] "ProjectileAirResistance.dat" \using 1:4 with lines title "v_x(t)",0
  gnuplot> replot "ProjectileAirResistance.dat" \using 1:5 with lines title "v_y(t)",-g/k
  gnuplot> plot "ProjectileAirResistance.dat" \using 2:3 with lines title "With air resistance k=5.0"
  gnuplot> replot "Projectile.dat"
```
Figure 2.10: Trajectories of the particles shot with $v_0 = 10.0$, $\theta = \pi/4$ in the absence of air resistance and when the air resistance is present in the form $\vec{F} = -mk\vec{v}$ with $k = 5.0$.

Long commands have been continued to the next line as before. We defined the gnuplot variables $v_{0x}$, $v_{0y}$, $g$ and $k$ to have the values that we used when running the program. We can use them in order to construct the asymptotes of the plotted functions of time. The results are shown in figures 2.9 and 2.10.

The last example of this section will be that of the anisotropic harmonic oscillator. The force on the particle is

$$F_x = -m\omega_1^2 x \quad F_y = -m\omega_2^2 y$$

(2.11)

where the “spring constants” $k_1 = m\omega_1^2$ and $k_2 = m\omega_2^2$ are different in the directions of the axes $x$ and $y$. The solutions of the dynamical equations of motion for $x(0) = A$, $y(0) = 0$, $v_x(0) = 0$ and $v_y(0) = \omega_2 A$ are

$$x(t) = A \cos(\omega_1 t) \quad y(t) = A \sin(\omega_2 t)$$

$$v_x(t) = -\omega_1 A \sin(\omega_1 t) \quad v_y(t) = \omega_2 A \cos(\omega_2 t).$$

(2.12)

If the angular frequencies $\omega_1$ and $\omega_2$ satisfy certain relations, the trajectories of the particle are closed and self intersect at a given number of
points. The proof of these relations, as well as their numerical confirmation, is left as an exercise for the reader. The program listed below is in the file Lissajoux.f90:

```
!============================================================================
!File Lissajoux.f90
!Lissajous curves (special case)
!x(t) = cos(o1 t), y(t) = sin(o2 t)
!
program Lissajous
  implicit none
!
  !Declaration of variables
  real x0,y0,R,x,y,vx,vy,t,t0,tf,dt
  real o1,o2,T1,T2
  real , parameter :: PI=3.1415927
!
  !Ask user for input:
  print *,'# Enter omega1 and omega2:'
  read *,o1,o2
  print *,'# Enter tf,dt:'
  read *,tf,dt
  print '*',# t0=',0.0,tf=',tf,' dt=',dt
!
  !Initialize
  if(o1.le.0.0 .or. o2.le.0.0) stop 'omega1 or omega2<=0'
  T1 = 2.0*PI/o1
  T2 = 2.0*PI/o2
  open(unit=11, file='Lissajous.dat')
!
  !Compute:
  t = 0.0
  do while(t .le. tf)
    x = cos(o1*t)
    y = sin(o2*t)
    vx = -o1*sin(o1*t)
    vy = o2*cos(o2*t)
    write(11,*),t,x,y,vx,vy
    t = t + dt
  enddo
  close(11)
end program Lissajous
```

We have set \( A = 1 \) in the program above. The user must enter the two angular frequencies \( \omega_1 \) and \( \omega_2 \) and the corresponding times. A typical
CHAPTER 2. KINEMATICS

  gnuplot> t0=0;tf=10;dt=0.1
  gnuplot> load "animate2D.gnu"

The results for $\omega_1 = 3$ and $\omega_2 = 5$ are shown in figure 2.11.

![Graph](image)

Figure 2.11: The trajectory of the anisotropic oscillator with $\omega_1 = 3$ and $\omega_2 = 5$. 
2.2. Motion in Space

By slightly generalizing the methods described in the previous section, we will study the motion of a particle in three dimensional space. All we have to do is to add an extra equation for the coordinate \( z(t) \) and the component of the velocity \( v_z(t) \). The structure of the programs will be exactly the same as before.

Figure 2.12: The conical pendulum of the program ConicalPendulum.f90.

The first example is the conical pendulum, which can be seen in figure 2.12. The particle moves on the \( xy \) plane with constant angular velocity \( \omega \). The equations of motion are derived from the relations

\[
T_z = T \cos \theta = mg \quad T_{xy} = T \sin \theta = m \omega^2 r, \tag{2.13}
\]

where \( r = l \sin \theta \). Their solution is

\[
\begin{align*}
x(t) &= r \cos \omega t \\
y(t) &= r \sin \omega t \\
z(t) &= -l \cos \theta,
\end{align*}
\]

One has to choose appropriate initial conditions. Exercise: find them!
where we have to substitute the values
\[
\cos \theta = \frac{g}{\omega^2 l} \\
\sin \theta = \sqrt{1 - \cos^2 \theta} \\
r = \frac{g \sin \theta}{\omega^2 \cos \theta}.
\] (2.15)

For the velocity components we obtain
\[
v_x = -r \omega \sin \omega t \\
v_y = r \omega \cos \omega t \\
v_z = 0.
\] (2.16)

Therefore we must have
\[\omega \geq \omega_{\text{min}} = \sqrt{\frac{g}{l}},\] (2.17)

and when \(\omega \to \infty, \theta \to \pi/2\).

In the program that we will write, the user must enter the parameters \(l, \omega, \) the final time \(t_f\) and the time step \(\delta t\). We take \(t_0 = 0\). The convention that we follow for the output of the results is that they should be written in a file where the first 7 columns are the values of \(t, x, y, z, v_x, v_y\) and \(v_z\). Each line in this file is long and, in order to prevent Fortran from breaking it into two separate lines, we have to give an explicit format specification. See the discussion on page \textbf{48}. The full program is listed below:

```fortran
! File ConicalPendulum.f90
! Set pendulum angular velocity omega and display motion in 3D
!
program ConicalPendulum
   implicit none
!
! Declaration of variables
   real :: l,r,x,y,z,vx,vy,vz,t,tf,dt
   real :: theta,cos_theta,sin_theta,omega
   real, parameter :: PI=3.1415927,g=9.81
!
! Ask user for input:
   print *,'# Enter l,omega:'
   read *,l,omega
   print *,'# Enter tf,dt:'
```
2.2. MOTION IN SPACE

```fortran
read *, tf, dt
print *, '# l= ', l, ' omega= ', omega
print *, '# T= ', 2.0*PI/omega, ' omega_min= ', sqrt(g/l)
print *, '# t0= ', 0.0, ' tf= ', tf, ' dt= ', dt
!
! Initialize
!cos_theta = g/(omega^2*l)
if (cos_theta .ge. 1) stop 'cos(theta)>= 1'
sin_theta = sqrt(1.0-cos_theta*cos_theta)
z = -g/(omega*omega) !they remain constant through
vz = 0.0 !the motion
r = g/(omega*omega)*sin_theta/cos_theta
open(unit=11, file='ConicalPendulum.dat')
!
! Compute:
! t = 0.0
! do while(t .le. tf)
x = r*cos(omega*t)
y = r*sin(omega*t)
vx = -r*sin(omega*t)*omega
vy = r*cos(omega*t)*omega
write(11,100) t, x, y, z, vx, vy, vz
! enddo
close(11)
100 FORMAT(20G15.7)
end program ConicalPendulum
```

In order to compile and run the program we can use the commands shown below:

```
> gfortran ConicalPendulum.f90 -o cpd
> ./cpd
# Enter l, omega:
1.0 6.28
# Enter tf, dt:
10.0 0.01
# l= 1.0, omega= 6.28000021
# T= 1.00050724, omega_min= 3.132092
# t0= 0.0, tf= 10.0, dt= 0.00999999978
```

The results are recorded in the file ConicalPendulum.dat. In order to plot the functions \(x(t), y(t), z(t), v_x(t), v_y(t), v_z(t)\) we give the following gnuplot commands:

```
> gnuplot
gnuplot> plot "ConicalPendulum.dat" u 1:2 w l t "x(t)"
```
The results are shown in figure 2.13. In order to make a three dimensional plot of the trajectory, we should use the gnuplot command splot:

```bash
gnuplot> splot "ConicalPendulum.dat" u 2:3:4 w l t "r(t)"
```

The result is shown in figure 2.14. We can click on the trajectory and rotate it and view it from a different angle. We can change the plot limits with the command:

```bash
gnuplot> splot [-1.1:1.1][-1.1:1.1][-0.3:0.0] \
"ConicalPendulum.dat" using 2:3:4 w l t "r(t)"
```

We can animate the trajectory of the particle by using the file animate3D.gnu from the accompanying software. The commands are similar to the ones we had to give in the two dimensional case for the planar trajectories when we used the file animate2D.gnu:

```bash
gnuplot> file = "ConicalPendulum.dat"
gnuplot> set xrange [-1.1:1.1]; set yrange [-1.1:1.1] 
set zrange [-0.3:0] 
t0=0;tf=10;dt=0.1 
load "animate3D.gnu"
```
2.2. MOTION IN SPACE

Figure 2.14: The plot of the particle trajectory $\vec{r}(t)$ of the program ConicalPendulum.f90 for $\omega = 6.28$, $l = 1.0$. We can click and drag with the mouse on the window and rotate the curve and see it from a different angle. At the bottom left of the window, we see the viewing direction, given by the angles $\theta = 55.0$ degrees (angle with the $z$ axis) and $\phi = 62$ degrees (angle with the $x$ axis).

The result can be seen in figure 2.15. The program animate3D.gnu can be used on the data file of any program that prints $t \, x \, y \, z$ as the first words on each of its lines. All we have to do is to change the value of the file variable in gnuplot.

Next, we will study the trajectory of a charged particle in a homogeneous magnetic field $\vec{B} = B\hat{z}$. At time $t_0$, the particle is at $\vec{r}_0 = x_0\hat{x}$ and its velocity is $\vec{v}_0 = v_{0x}\hat{y} + v_{0z}\hat{z}$, see figure 2.16. The magnetic force on the particle is $\vec{F} = q(\vec{v} \times \vec{B}) = qBv_y\hat{x} - qBv_x\hat{y}$ and the equations of motion are

\begin{align*}
    a_x &= \frac{dv_x}{dt} = \omega v_y \\
    a_y &= \frac{dv_y}{dt} = -\omega v_x \\
    a_z &= 0.
\end{align*}

By integrating the above equations with the given initial conditions we obtain

\begin{align*}
    v_x(t) &= v_{0y}\sin\omega t \\
    v_y(t) &= v_{0y}\cos\omega t \\
    v_z(t) &= v_{0z}.
\end{align*}
Integrating once more, we obtain the position of the particle as a function of time

\[
\begin{align*}
    x(t) &= \left( x_0 + \frac{v_0 y}{\omega} \right) - \frac{v_0 y}{\omega} \cos \omega t = x_0 \cos \omega t \\
    y(t) &= \frac{v_0 y}{\omega} \sin \omega t = -x_0 \sin \omega t \quad \mu \varepsilon \quad x_0 = -\frac{v_0 y}{\omega} \\
    z(t) &= v_0 z t,
\end{align*}
\]

where we have chosen \( x_0 = -v_0 y / \omega \). This choice places the center of the circle, which is the projection of the trajectory on the \( xy \) plane, to be at the origin of the coordinate system. The trajectory is a helix with radius \( R = -x_0 \) and pitch \( v_0 z T = 2\pi v_0 z / \omega \).

We are now ready to write a program that calculates the trajectory given by (2.20). The user enters the parameters \( v_0 \) and \( \theta \), shown in figure 2.16, as well as the angular frequency \( \omega \) (Larmor frequency). The components of the initial velocity are \( v_0 y = v_0 \cos \theta \) and \( v_0 z = v_0 \sin \theta \). The initial position is calculated from the equation \( x_0 = -v_0 y / \omega \). The program can be found in the file ChargeInB.f90:
2.2. MOTION IN SPACE

Figure 2.16: A particle at time $t_0 = 0$ is at the position $\vec{r}_0 = x_0 \hat{x}$ with velocity $\vec{v}_0 = v_0 y \hat{y} + v_0 z \hat{z}$ in a homogeneous magnetic field $\vec{B} = B \hat{z}$.

```

```

A typical session in which we calculate the trajectories shown in figures 2.17 and 2.18 is shown below:

![Graphs of x(t), y(t), z(t), v_x(t), v_y(t), v_z(t)](image)

Figure 2.17: The plots of the x(t), y(t), z(t), v_x(t), v_y(t), v_z(t) functions calculated by the program in ChargeInB.f90 for \( \omega = 6.28 \), \( x_0 = 1.0 \), \( \theta = 20 \) degrees.
2.3. TRAPPED IN A BOX

In this section we will study the motion of a particle that is free, except when bouncing elastically on a wall or on certain obstacles. This motion is calculated by approximate algorithms that introduce systematic errors. These types of errors are also encountered in the study of more complicated dynamics, but the simplicity of the problem will allow us to control them in a systematic and easy to understand way.

¹⁵In the previous sections, our calculations had a small systematic error due to the approximate nature of numerical floating point operations which approximate exact real number calculations. But the algorithms used were not introducing systematic errors like in the cases discussed in this section.

2.3.1 The One Dimensional Box

The simplest example of such a motion is that of a particle in a “one dimensional box”. The particle moves freely on the $x$ axis for $0 < x < L$, as can be seen in figure 2.19. When it reaches the boundaries $x = 0$ and $x = L$ it bounces and its velocity instantly reversed. Its potential energy is

$$V(x) = \begin{cases} 0 & 0 < x < L \\ +\infty & \text{elsewhere} \end{cases},$$

which has the shape of an infinitely deep well. The force $F = -dV(x)/dx = 0$ within the box and $F = \pm\infty$ at the position of the walls.

Initially we have to know the position of the particle $x_0$ as well as its velocity $v_0$ (the sign of $v_0$ depends on the direction of the particle’s motion) at time $t_0$. As long as the particle moves within the box, its motion is free and

$$x(t) = x_0 + v_0(t - t_0)$$
$$v(t) = v_0.$$
For a small enough change in time $\delta t$, so that there is no bouncing on the wall in the time interval $(t, t + \delta t)$, we have that

\[
\begin{align*}
  x(t + \delta t) &= x(t) + v(t)\delta t \\
  v(t + \delta t) &= v(t).
\end{align*}
\]

Therefore we could use the above relations in our program and when the particle bounces off a wall we could simply reverse its velocity $v(t) \to -v(t)$. The devil is hiding in the word “when”. Since the time interval $\delta t$ is finite in our program, there is no way to know the instant of the collision with accuracy better than $\sim \delta t$. However, our algorithm will change the direction of the velocity at time $t + \delta t$, when the particle will have already crossed the wall. This will introduce a systematic error, which is expected to decrease with decreasing $\delta t$. One way to implement the above idea is by constructing the loop

```fortran
do while(t .le. tf)
    write(11,*)t,x,v
    x = x + v*dt
    t = t + dt
    if(x .lt. 0.0 .or. x .gt. L) v = -v
endo
```

where the last line gives the testing condition for the wall collision and the subsequent change of the velocity.

The full program that realizes the proposed algorithm is listed below and can be found in the file `box1D_1.f90`. The user can set the size of the box $L$, the initial conditions $x_0$ and $v_0$ at time $t_0$, the final time $tf$ and the time step $dt$:
CHAPTER 2. KINEMATICS

File box1D_1.f90
Motion of a free particle in a box 0<x<L
Use integration with time step dt: x = x + v*dt

program box1D
  implicit none
!
! Declaration of variables
  real :: L, x0, v0, t0, tf, dt, t, x, v
!
! Ask user for input:
  print *, '# Enter L:'
  read *, L
  print *, '# L = ', L
  if (L .le. 0.0) stop 'L must be positive.'
  print *, '# Enter x0,v0:'
  read *, x0, v0
  print *, '# x0= ', x0, ', v0= ', v0
  if(x0 .lt. 0.0 .or. x0 .gt. L) stop 'illegal value of x0.'
  if(v0 .eq. 0.0) stop 'illegal value of v0 = 0.'
  print *, '# Enter t0,tf,dt:'
  read *, t0, tf, dt
  print *, '# t0= ', t0, ', tf= ', tf, ', dt= ', dt
!
! Initialize
  t = t0
  x = x0
  v = v0
  open (unit=11, file='box1D_1.dat')
!
! Compute:
  do while (t .le. tf)
    write (11,*) t, x, v
    x = x + v*dt
    t = t + dt
    if(x .lt. 0.0 .or. x .gt. L) v = -v
  enddo
  close (11)
end program box1D

The computed data is recorded in the file box1D_1.dat in three columns. Compiling, running and plotting the trajectory using gnuplot can be done as follows:

> gfortran box1D_1.f90 -o box1
> ./box1
  # Enter L:
2.3. TRAPPED IN A BOX

10
# L = 10.
# Enter x0,v0:
0 1.0
# x0= 0. v0= 1.
# Enter t0,tf,dt:
0 100 0.01
# t0= 0. tf= 100. dt= 0.00999999978

> gnuplot
gnuplot> plot "box1D_1.dat" using 1:2 w l title "x(t)",
0 notitle,10 notitle

> gnuplot> plot [:][-1.2:1.2] "box1D_1.dat" \ using 1:3 w l title "v(t)"

Figure 2.20: The trajectory $x(t)$ of a particle in a box with $L = 10$, $x_0 = 0.0$, $v_0 = 1.0$, $t_0 = 0$, $\delta t = 0.01$. The plot to the right magnifies a detail when $t \approx 90$ which exposes the systematic errors in determining the exact moment of the collision of the particle with the wall at $t_k = 90$ and the corresponding maximum value of $x(t)$, $x_m = L = 10.0$.

The trajectory $x(t)$ is shown in figure 2.20. The effects of the systematic errors can be easily seen by noting that the expected collisions occur every $T/2 = L/v = 10$ units of time. Therefore, on the plot to the right of figure 2.20, the reversal of the particle’s motion should have occurred at $t = 90$, $x = L = 10$.

The reader should have already realized that the above mentioned error can be made to vanish by taking arbitrarily small $\delta t$. Therefore, we naively expect that as long as we have the necessary computer power to take $\delta t$ as small as possible and the corresponding time intervals as many as possible, we can achieve any precision that we want. Well, that is true only up to a point. The problem is that the next position is determined by the addition operation $x+v*\delta t$ and the next moment in
time by \( t + dt \). Floating point numbers of the \texttt{REAL} type have a maximum accuracy of approximately 7 significant decimal digits. Therefore, if the operands \( x \) and \( v \cdot dt \) are real numbers differing by more than 7 orders of magnitude (\( v \cdot dt \lesssim 10^{-7} \cdot x \)), the effect of the addition \( x + v \cdot dt = x \), which is null! The reason is that the floating point unit of the processor has to convert both numbers \( x \) and \( v \cdot dt \) into a representation having the same exponent and in doing so, the corresponding significant digits of the smaller number \( v \cdot dt \) are lost. The result is less catastrophic when \( v \cdot dt \lesssim 10^{-a} \cdot x \) with \( 0 < a < 7 \), but some degree of accuracy is also lost at each addition operation. And since we have accumulation of such errors over many intervals \( t \rightarrow t + dt \), the error can become significant and destroy our calculation for large enough times. A similar error accumulates in the determination of the next instant of time \( t + dt \), but we will discuss below how to make this contribution to the total error negligible. The above mentioned errors can become less detrimental by using floating point numbers of greater accuracy than the \texttt{REAL} type. For example \texttt{REAL(8)} numbers have approximately 16 significant decimal digits. But again, the precision is finite and the same type of errors are there only to be revealed by a more demanding and complicated calculation.

The remedy to such a problem can only be a change in the algorithm. This is not always possible, but in the case at hand this is easy to do. For example, consider the equation that gives the position of a particle in free motion

\[
x(t) = x_0 + v_0(t - t_0).
\]

Let's use the above relation for the parts of the motion between two collisions. Then, all we have to do is to reverse the direction of the motion and reset the initial position and time to be the position and time of the collision. This can be done by using the loop:

```fortran
  t = t0
  do while(t .le. tf)
    x = x0 + v0*(t-t0)
    write(11,*)t,x,v0
    if( x .lt. 0.0 .or. x .gt. L)then
      x0 = x
      t0 = t
      v0 = -v0
    endif
    t = t + dt
  enddo
```

In the above algorithm, the error in the time of the collision is not van-
ishing but we don’t have the “instability” problem of the $dt \to 0$ limit. Therefore we can isolate and study the effect of each type of error. The full program that implements the above algorithm is given below and can be found in the file box1D_2.f90:

![File box1D_2.f90]

Motion of a free particle in a box $0 < x < L$

Use constant velocity equation: $x = x_0 + v_0(t-t_0)$

Reverse velocity and redefine $x_0, t_0$ on boundaries

---

```fortran
program box1D
    implicit none

    ! Declaration of variables
    real :: L, x0, v0, t0, tf, dt, t, x, v

    ! Ask user for input:
    print *, '# Enter L:'
    read *, L
    print *, '# L = ', L
    if (L .le. 0.0) stop 'L must be positive.'
    print *, '# Enter x0,v0:'
    read *, x0, v0
    print *, '# x0= ', x0, ' v0= ', v0
    if(x0 .lt. 0.0 .or. x0 .gt. L) stop 'illegal value of x0.'
    if(v0 .eq. 0.0) stop 'illegal value of v0 = 0.'
    print *, '# Enter t0,tf,dt:'
    read *, t0, tf, dt
    print *, '# t0= ', t0, ' tf= ', tf, ' dt= ', dt

    ! Initialize
    t = t0
    open(unit=11, file='box1D_2.dat')

    ! Compute:
    do while(t .le. tf)
        x = x0 + v0*(t-t0)
        write(11,*) t, x, v0
        if(x .lt. 0.0 .or. x .gt. L) then
            x0 = x
            t0 = t
            v0 = -v0
        endif
        t = t + dt
    enddo
```

We still have this problem in the $t = t + dt$ operation. See discussion in the next section.
Compiling and running the above program is done as before and the results are stored in the file `box1D_2.dat`. The algorithm can be improved in order to compute the exact solution. We leave that as an exercise for the reader.¹⁷

### 2.3.2 Errors

In this section we will study the effect of the systematic errors that we encountered in the previous section in more detail. We considered two types of errors: First, the systematic error of determining the instant of the collision of the particle with the wall. This error is reduced by taking a smaller time step `δt`. Then, the systematic error that accumulates with each addition of two numbers with increasing difference in their orders of magnitude. This error is increased with decreasing `δt`. The competition of the two effects makes the optimal choice of `δt` the result of a careful analysis. Such a situation is found in many interesting problems, therefore it is quite instructive to study it in more detail.

When the exact solution of the problem is not known, the systematic errors are controlled by studying the behavior of the solution as a function of `δt`. If the solutions are converging in a region of values of `δt`, one gains confidence that the true solution has been determined up to the accuracy of the convergence.

In the previous sections, we studied two different algorithms, programmed in the files `box1D_1.f90` and `box1D_2.f90`. We will refer to them as “method 1” and “method 2” respectively. We will study the convergence of the results as `δt → 0` by fixing all the parameters except `δt` and then study the dependence of the results on `δt`. We will take `L = 10`, `v_0 = 1.0`, `x_0 = 0.0`, `t_0 = 0.0`, `t_f = 95.0`, so that the particle will collide with the wall every 10 units of time. We will measure the position of the particle `x(t ≈ 95)`¹⁸ as a function of `δt` and study its convergence to a limit as `δt → 0`.

The analysis requires a lot of repetitive work: Compiling, setting the parameter values, running the program and calculating the value of `x(t ≈ 95)`

---

¹⁷See the file `box1D_3.dat`.
¹⁸Note the `≈`!
¹⁹Of course we know the answer: `x(95) = 5`.  

95) for many values of $\delta t$. We write the values of the parameters read by
the program in a file box1D_anal.in:

| 10 | L |
| 0 | 1.0 | x0  v0 |
| 0 | 95  0.05 | t0  tf  dt |

Then we compile the program

```
> gfortran box1D_1.f90 -o box
```

and run it with the command:

```
> cat box1D_anal.in | ./box
```

By using the pipe |, we send the contents of box1D_anal.in to the stdin
of the command ./box by using the command cat. The result \( x(t \approx 95) \)
can be found in the last line of the file box1D_1.dat:

```
> tail -n 1 box1D_1.dat
94.9511948 5.45000267 -1.
```

The third number in the above line is the value of the velocity. In a
file box1D_anal.dat we write $\delta t$ and the first two numbers coming out
from the command tail. Then we decrease the value $\delta t \rightarrow \delta t/2$ in
the file box1D_anal.in and run again. We repeat for 12 more times
until $\delta t$ reaches the value $0.000012$. We do the same $0.025$ using method 2
and we place the results for $x(t \approx 95)$ in two new columns in the file
box1D_anal.dat. The result is

```
#  #  #  #
#  #  #  #
0.050000 94.95119 5.450003 5.550126
0.025000 94.97849 5.275011 5.174837
0.012500 94.99519 5.124993 5.099736
0.006250 94.99850 4.987460 5.063134
0.003125 94.99734 5.021894 5.035365
```

20 Try the command sed ‘s/0.05/0.025/’ box1D_anal.in | ./box by changing
0.025 with the desired value of $\delta t$.

21 See the shell script box1D_anal.csh as a suggestion on how to automate this boring
process.
0.001563 94.99923 5.034538 5.017764
0.000781 94.99939 4.919035 5.011735
0.000391 94.99979 4.695203 5.007493
0.000195 95.00000 5.434725 5.001935
0.000098 94.99991 5.528124 5.000745
0.000049 94.99998 3.358000 5.000330
0.000024 94.99998 2.724212 5.000232
0.000012 94.99999 9.240705 5.000158

Convergence is studied in figure 2.21. The 1st method maximizes its accuracy for $\delta t \approx 0.01$, whereas for $\delta t < 0.0001$ the error becomes $> 10\%$ and the method becomes useless. The 2nd method has much better behavior that the 1st one.

We observe that as $\delta t$ decreases, the final value of $t$ approaches the expected $t_f = 95$. Why don’t we obtain $t = 95$, especially when $t/\delta t$ is an integer? How many steps does it really take to reach $t \approx 95$, when the expected number of those is $\approx 95/\delta t$? Each time you take a measurement, issue the command

$$\texttt{wc -l box1D_1.dat}$$

which measures the number of lines in the file box1D_1.dat and compare this number with the expected one. The result is interesting:

<table>
<thead>

</tbody>
</table>

where the second column has the number of steps computed by the program and the third one has the expected number of steps. We observe that the accuracy decreases with decreasing $\delta t$ and in the end the difference is about 5%! Notice that the last line should have given
2.3. TRAPPED IN A BOX

\( t_f = 0.000012 \times 7540956 \approx 90.5 \), an error comparable to the period of the particle’s motion.

We conclude that one important source of accumulation of systematic errors is the calculation of time. This type of errors become more significant with decreasing \( \delta t \). We can improve the accuracy of the calculation significantly if we use the multiplication \( t = t_0 + i \times \delta t \) instead of the addition \( t = t + \delta t \), where \( i \) is a step counter:

\[
\begin{align*}
!t &= t + \delta t \quad ! \text{Not accurate, avoid} \\
t &= t_0 + i \times \delta t \quad ! \text{Better accuracy, prefer}
\end{align*}
\]

The main loop in the program box1D_1.f90 becomes:

```
t = t0
x = x0
v = v0
i = 0
do while(t .le. tf)
   write(11,*)t,x,v
   i = i + 1
   x = x + v*\delta t
   t = t0 + i*\delta t
   if(x .lt. 0.0 .or. x .gt. L) v = -v
endo```

The full program can be found in the file box1D_4.f90 of the accompanying software. We call this “method 3”. We perform the same change in the file box1D_2.f90, which we store in the file box1D_5.f90. We call this “method 4”. We repeat the same analysis using methods 3 and 4 and we find that the problem of calculating time accurately practically vanishes. The result of the analysis can be found on the right plot of figure 2.21. Methods 2 and 4 have no significant difference in their results, whereas methods 1 and 3 do have a dramatic difference, with method 3 decreasing the error more than tenfold. The problem of the increase of systematic errors with decreasing \( \delta t \) does not vanish completely due to the operation \( x = x + v \times \delta t \). This type of error is harder to deal with and one has to invent more elaborate algorithms in order to reduce it significantly. This will be discussed further in chapter 4.

2.3.3 The Two Dimensional Box

A particle is confined to move on the plane in the area \( 0 < x < L_x \) and \( 0 < y < L_y \). When it reaches the boundaries of this two dimensional
box, it bounces elastically off its walls. The particle is found in an infinite depth orthogonal potential well. The particle starts moving at time $t_0$ from $(x_0, y_0)$ and our program will calculate its trajectory until time $t_f$ with time step $\delta t$. Such a trajectory can be seen in figure 2.23.

If the particle’s position and velocity are known at time $t$, then at time $t + \delta t$ they will be given by the relations

$$
\begin{align*}
  x(t + \delta t) &= x(t) + v_x(t)\delta t \\
  y(t + \delta t) &= y(t) + v_y(t)\delta t \\
  v_x(t + \delta t) &= v_x(t) \\
  v_y(t + \delta t) &= v_y(t).
\end{align*}
$$

(2.25)

The collision of the particle off the walls is modeled by reflection of the normal component of the velocity when the respective coordinate of the particle crosses the wall. This is a source of the systematic errors that we discussed in the previous section. The central loop of the program is:

```fortran
i = i + 1
x = x + vx*dt
y = y + vy*dt
if (x .lt. 0.0 .or. x .gt. Lx) vx = -vx
if (y .lt. 0.0 .or. y .gt. Ly) vy = -vy
```

The full program can be found in the file `box2D_1.f90`. Notice that we introduced two counters $n_x$ and $n_y$ of the particle’s collisions with the walls:
2.3. TRAPPED IN A BOX

Motion of a free particle in a box

\(0 < x < L_x\)

\(0 < y < L_y\)

Use integration with time step \(dt\):

\[
x = x + vx*dt
y = y + vy*dt
\]

Program box2D

```fortran
program box2D
  implicit none
  ! Declaration of variables
  real(8) :: Lx, Ly, x0, y0, v0x, v0y, t0, tf, dt, t, x, y, vx, vy
  integer :: i, nx, ny
  ! Ask user for input:
  print *, '# Enter Lx, Ly:'
  read *, Lx, Ly
  if (Lx .le. 0.0) stop 'Lx must be positive.'
  if (Ly .le. 0.0) stop 'Ly must be positive.'
  print *, '# Enter x0, y0, v0x, v0y:'
  read *, x0, y0, v0x, v0y
  if (x0 .lt. 0.0 .or. x0 .gt. Lx) stop 'illegal value x0'
  if (y0 .lt. 0.0 .or. y0 .gt. Ly) stop 'illegal value y0'
  print *, '# Enter t0, tf, dt:'
  read *, t0, tf, dt
  if (t0 .le. tf) then
    open(unit=11, file='box2D_1.dat')
  endif
  ! Initialize
  i = 0
  nx = 0 ; ny = 0
  t = t0
  x = x0 ; y = y0
  vx = v0x ; vy = v0y
  ! Compute:
  do while(t .le. tf)
    write(11,*) t, x, y, vx, vy
    i = i + 1
    t = t0 + i * dt
    x = x + vx*dt
    y = y + vy*dt
    if (x .lt. 0.0 .or. x .gt. Lx) then
      vx = -vx
      nx = nx + 1
    endif
    if (y .lt. 0.0 .or. y .gt. Ly) then
      vy = -vy
      ny = ny + 1
    endif
    write(11,*) t, x, y, vx, vy
  end do
end program box2D
```
A typical session for the study of a particle’s trajectory could be:

```fortran
vy = -vy
ny = ny + 1
endif
doto
close(1)
print *,#' Number of collisions:'
print *,#' nx= ',nx,' ny= ',ny
end program box2D
```

Notice the last line of output from the program: The particle bounces off the vertical walls 6 times ($nx=6$) and from the horizontal ones 13 ($ny=13$). The gnuplot commands construct the diagrams displayed in figures 2.22 and 2.23.

In order to animate the particle’s trajectory, we can copy the file box2D_animate.gnu of the accompanying software to the current directory and give the gnuplot commands:

```bash
gnuplot> file = "box2D_1.dat"
gnuplot> Lx = 10 ; Ly = 5
gnuplot> t0 = 0 ; tf = 50; dt = 1
gnuplot> load "box2D_animate.gnu"
gnuplot> t0 = 0 ; dt = 0.5; load "box2D_animate.gnu"
```

The last line repeats the same animation at half speed. You can also
2.4 Applications

In this section we will study simple examples of motion in a box with different types of obstacles. We will start with a game of ... mini golf. The player shoots a (point) “ball” which moves in an orthogonal box of linear dimensions $L_x$ and $L_y$ and which is open on the $x = 0$ side. In the box there is a circular “hole” with center at $(x_c, y_c)$ and radius $R$. If the “ball” falls in the “hole”, the player wins. If the ball leaves out of the box through its open side, the player loses. In order to check if the ball is in the hole when it is at position $(x, y)$, all we have to do is to check whether $(x - x_c)^2 + (y - y_c)^2 \leq R^2$.

Initially we place the ball at the position $(0, L_y/2)$ at time $t_0 = 0$. The player hits the ball which leaves with initial velocity of magnitude $v_0$ at an angle $\theta$ degrees with the $x$ axis. The program is found in the file MiniGolf.f90 and is listed below:

use the file animate2D.gnu discussed in section 2.1.1. We add new commands in the file box2D_animate.gnu so that the plot limits are calculated automatically and the box is drawn on the plot. The arrow drawn is not the position vector with respect to the origin of the coordinate axes, but the one connecting the initial with the current position of the particle.

The next step should be to test the accuracy of your results. This can be done by generalizing the discussion of the previous section and is left as an exercise for the reader.

Figure 2.22: The results for the trajectory of a particle in a two dimensional box given by the program box2D_1.f90. The parameters are $L_x = 10, L_y = 5, x_0 = 5, y_0 = 0, v_{0x} = 1.27, v_{0y} = 1.33, t_0 = 0, t_f = 50, \delta t = 0.01$. 
Figure 2.23: The trajectory of the particle of figure 2.22 until $t = 48$. The origin of the arrow is at the initial position of the particle and its end is at its current position. The bold lines mark the boundaries of the box.

\[ \text{print *,'\# Result= ',result,' nx= ',nx,' ny= ',ny} \]

end program MiniGolf

In order to run it, we can use the commands:

```fortran
> gfortran MiniGolf.f90 -o mg
> ./mg
# Enter Lx, Ly:
10 5
# Lx = 10. Ly = 5.
# Enter hole position and radius: (xc,yc), R:
8 2.5 0.5
# (xc,yc) = ( 8. , 2.5 ) R = 0.5
```
2.4. APPLICATIONS

You should construct the plots of the position and the velocity of the particle. You can also use the animation program found in the file MiniGolf_animate.gnu for fun. Copy it from the accompanying software to the current directory and give the gnuplot commands:

```
# Enter v0, theta(degrees):
1 80
# v0= 1. theta= 80. degrees
# Enter dt:
0.01
# dt= 0.01
# x0= 1.E-05 y0= 2.5 v0x= 0.173648178 v0y= 0.984807753
# Number of collisions:
# Result= Success nx= 0 ny= 9
```

The results are shown in figure 2.24.

The next example will be three dimensional. We will study the motion of a particle confined within a cylinder of radius $R$ and height $L$. The collisions of the particle with the cylinder are elastic. We take the axis of the cylinder to be the $z$ axis and the two bases of the cylinder to be located at $z = 0$ and $z = L$. This is shown in figure 2.26.

The collisions of the particle with the bases of the cylinder are easy to program: we follow the same steps as in the case of the simple box. For the collision with the cylinder’s side, we consider the projection of the motion on the $x – y$ plane. The projection of the particle moves within a circle of radius $R$ and center at the intersection of the $z$ axis with the plane. This is shown in figure 2.25. At the collision, the $r$ component of the velocity is reflected $v_r \rightarrow -v_r$, whereas $v_\theta$ remains the same. The velocity of the particle before the collision is

\[
\vec{v} = v_x \hat{x} + v_y \hat{y} = v_r \hat{r} + v_\theta \hat{\theta}
\]  

and after the collision is

\[
\vec{v}' = v'_x \hat{x} + v'_y \hat{y} = -v_r \hat{r} + v_\theta \hat{\theta}
\]
CHAPTER 2. KINEMATICS

From the relations
\[ \begin{align*}
\dot{\mathbf{r}} &= \cos \theta \dot{x} + \sin \theta \dot{y} \\
\dot{\theta} &= -\sin \theta \dot{x} + \cos \theta \dot{y},
\end{align*} \] (2.28)

and \( v_r = \vec{v} \cdot \mathbf{r}, \quad v_\theta = \vec{v} \cdot \dot{\theta} \), we have that
\[ \begin{align*}
v_r &= v_x \cos \theta + v_y \sin \theta \\
v_\theta &= -v_x \sin \theta + v_y \cos \theta.
\end{align*} \] (2.29)

The inverse relations are
\[ \begin{align*}
v_x &= v_r \cos \theta - v_\theta \sin \theta \\
v_y &= v_r \sin \theta + v_\theta \cos \theta.
\end{align*} \] (2.30)

With the transformation \( v_r \to -v_r \), the new velocity in Cartesian coordinates will be
\[ \begin{align*}
v'_x &= -v_r \cos \theta - v_\theta \sin \theta \\
v'_y &= -v_r \sin \theta + v_\theta \cos \theta.
\end{align*} \] (2.31)

The transformation \( v_x \to v'_x, \quad v_y \to v'_y \) will be performed in the subroutine \( \text{reflectVonCircle}(v_x, v_y, x, y, x_c, y_c, R) \). Upon entry to the subroutine, we provide the initial velocity \( (v_x, v_y) \), the collision point \( (x, y) \), the center of the circle \( (x_c, y_c) \) and the radius of the circle \( R \). Upon exit from the subroutine, \( (v_x, v_y) \) have been replaced with the new values \( (v'_x, v'_y) \).

The program can be found in the file \( \text{Cylinder3D.f90} \) and is listed below:

\begin{verbatim}
! File Cylinder3D.f90
! Motion of a free particle in a cylinder with axis the z-axis,
! radius R and 0<z<L
! Use integration with time step dt: x = x + vx*dt
! y = y + vy*dt
! z = z + vz*dt
! Use subroutine reflectVonCircle for collisions at r=R
!
program Cylinder3D

20 Of course one expects \( R^2 = (x - x_c)^2 + (y - y_c)^2 \), but because of systematic errors, we require \( R \) to be given.
21 Note that upon exit, the particle is also placed exactly on the circle.
\end{verbatim}
2.4. APPLICATIONS

Figure 2.25: The elastic collision of the particle moving within the circle of radius $R = |\vec{R}|$ and center $\vec{r}_c = x_c\hat{x} + y_c\hat{y}$ at the point $\vec{r} = x\hat{x} + y\hat{y}$. We have that $\vec{R} = (x - x_c)\hat{x} + (y - y_c)\hat{y}$. The initial velocity is $\vec{v} = v_r\hat{r} + v_\theta\hat{\theta}$ where $\hat{r} \equiv \vec{R}/R$. After reflecting $v_r \rightarrow -v_r$ the new velocity of the particle is $\vec{v}' = -v_r\hat{r} + v_\theta\hat{\theta}$.

subroutine reflectVonCircle (vx, vy, x, y, xc, yc, R)
implicit none
real(8) :: vx, vy, x, y, xc, yc, R
real(8) :: theta, cth, sth, vr, vth

theta = atan2 (y-yc, x-xc)
cth = cos(theta)
sth = sin(theta)
Notice that the function \( \text{atan2} \) is used for computing the angle \( \theta \). This function, when called with two arguments \( \text{atan2}(y, x) \), returns the angle \( \theta = \tan^{-1}(y/x) \) in radians. The correct quadrant of the circle where \((x, y)\) lies is chosen. The angle that we want to compute is given by \( \text{atan2}(y-yc, x-xc) \). Then we apply equations \((2.29)\) and \((2.31)\) and in the last two lines we enforce the particle to be at the point \((x_c+R \cos \theta, y_c+R \sin \theta)\), exactly on the circle.

\[
\begin{align*}
vr &= vx \cdot cth + vy \cdot sth \\
vth &= -vx \cdot sth + vy \cdot cth \\
vx &= -vr \cdot cth - vth \cdot sth \quad \text{reflect} \quad vr \rightarrow -vr \\
vy &= -vr \cdot sth + vth \cdot cth \\
x &= xc + R \cdot cth \quad \text{!put x,y on the circle} \\
y &= yc + R \cdot sth \\
\end{align*}
\]

end subroutine reflectVonCircle

Figure 2.26: The trajectory of a particle moving inside a cylinder with \( R = 10, L = 10 \), computed by the program Cylinder3D.f90. We have chosen \( \vec{r}_0 = 1.0\hat{x} + 2.2\hat{y} + 3.1\hat{z} \), \( \vec{v}_0 = 0.93\hat{x} - 0.89\hat{y} + 0.74\hat{z} \), \( t_0 = 0, t_f = 500.0, \delta t = 0.01 \).

A typical session is shown below:
In order to plot the position and the velocity as a function of time, we use the following gnuplot commands:

```gnuplot
> gfortran Cylinder3D.f90 -o cl
> ./cl
> # Enter R, L:
10.0 10.0
# R= 10. L= 10.
> # Enter x0, y0, z0, v0x, v0y, v0z:
1.0 2.2 3.1 0.93 -0.89 0.74
# x0= 1. y0= 2.2 z0= 3.1 rxy= 2.41660919
# v0x= 0.93 v0y= -0.89 v0z= 0.74
> # Enter t0, tf, dt:
0.0 500.0 0.01
# t0= 0. tf= 500. dt= 0.01
> # Number of collisions:
# nr= 33 nz= 37
```

In order to plot the position and the velocity as a function of time, we use the following gnuplot commands:

```gnuplot
gnuplot> file="Cylinder3D.dat"
```

```gnuplot
gnuplot> plot file using 1:2 with lines title "x(t)"
file using 1:3 with lines title "y(t)"
file using 1:4 with lines title "z(t)"
```

```gnuplot
gnuplot> plot file using 1:5 with lines title "v_x(t)"
file using 1:6 with lines title "v_y(t)"
file using 1:7 with lines title "v_z(t)"
```

We can also compute the distance of the particle from the cylinder’s axis
\[ r(t) = \sqrt{x(t)^2 + y(t)^2} \]
as a function of time using the command:

```gnuplot
gnuplot> plot file using 1:(sqrt($2**2+$3**2)) w l t "r(t)"
```

In order to plot the trajectory, together with the cylinder, we give the commands:

```gnuplot
gnuplot> L = 10 ; R = 10
```

```gnuplot
gnuplot> set urange [0:2.0*pi]
```

```gnuplot
gnuplot> set vrangle [0:L]
```

```gnuplot
gnuplot> set parametric
```

```gnuplot
gnuplot> splot file using 2:3:4 with lines notitle,\
R*cos(u),R*sin(u),v notitle
```

The command `set parametric` is necessary if one wants to make a parametric plot of a surface \( \vec{r}(u, v) = x(u, v) \hat{x} + y(u, v) \hat{y} + z(u, v) \hat{z} \). The cylinder (without the bases) is given by the parametric equations \( \vec{r}(u, v) = R \cos u \hat{x} + R \sin u \hat{y} + v \hat{z} \) with \( u \in [0, 2\pi] \), \( v \in [0, L] \).
2.4. APPLICATIONS

We can also animate the trajectory with the help of the gnuplot script file Cylinder3D_animate.gnu. Copy the file from the accompanying software to the current directory and give the gnuplot commands:

```gnuplot
R=10; L=10; t0=0; tf=500; dt=10
load "Cylinder3D_animate.gnu"
```

The result is shown in figure 2.26.

The last example will be that of a simple model of a spacetime wormhole. This is a simple spacetime geometry which, in the framework of the theory of general relativity, describes the connection of two distant areas in space which are asymptotically flat. This means, that far enough from the wormhole’s mouths, space is almost flat - free of gravity. Such a geometry is depicted in figure 2.27. The distance traveled by someone through the mouths could be much smaller than the distance traveled outside the wormhole and, at least theoretically, traversable wormholes could be used for interstellar/intergalactic traveling and/or communications between otherwise distant areas in the universe. Of course we should note that such macroscopic and stable wormholes are not known to be possible to exist in the framework of general relativity. One needs an exotic type of matter with negative energy density which has never been observed. Such exotic geometries may realize microscopically as quantum fluctuations of spacetime and make the small scale structure of the geometry a “spacetime foam”.

We will study a very simple model of the above geometry on the plane with a particle moving freely in it. We take the two dimensional plane and cut two equal disks of radius $R$ with centers at distance $d$ like in figure 2.28. We identify the points on the two circles such that the point 1 of the left circle is the same as the point 1 on the right circle, the point 2 on the left with the point 2 on the right etc. The two circles are given by the parametric equations $x(\theta) = d/2 + R \cos \theta$, $y(\theta) = R \sin \theta$, $-\pi < \theta \leq \pi$ for the right circle and $x(\theta) = -d/2 - R \cos \theta$, $y(\theta) = R \sin \theta$, $-\pi < \theta \leq \pi$ for the left. Points on the two circles with the same $\theta$ are identified. A particle entering the wormhole from the left circle with velocity $v$ is immediately exiting from the right with velocity $v'$ as shown in figure 2.28.

²⁵This idea can be found as an exercise in the excellent introductory general relativity textbook J. B. Hartle, “Gravity: An Introduction to Einstein’s General Relativity”, Addison Wesley 2003, Ch. 7, Ex. 25.
Then we will do the following:

1. Write a program that computes the trajectory of a particle moving in the geometry of figure 2.27. We set the limits of motion to be $-L/2 \leq x \leq L/2$ and $-L/2 \leq y \leq L/2$. We will use periodic boundary conditions in order to define what happens when the particle attempts to move outside these limits. This means that we identify the $x = -L/2$ line with the $x = +L/2$ line as well as the $y = -L/2$ line with the $y = +L/2$ line. The user enters the parameters $R$, $d$ and $L$ as well as the initial conditions $(x_0, y_0)$, $(v_0, \phi)$ where $\vec{v}_0 = v_0(\cos \phi \hat{x} + \sin \phi \hat{y})$. The user will also provide the time parameters $t_f$ and $dt$ for motion in the time interval $t \in [t_0 = 0, t_f]$ with step $dt$.

2. Plot the particle’s trajectory with $(x_0, y_0) = (0, -1)$, $(v_0, \phi) = (1, 10^\circ)$ $\mu s$ $t_f = 40$, $dt = 0.05$ in the geometry with $L = 20$, $d = 5$, $R = 1$.

3. Find a closed trajectory which does not cross the boundaries $|x| = L/2$, $|y| = L/2$ and determine whether it is stable under small perturbations of the initial conditions.

4. Find other closed trajectories that go through the mouths of the
2.4. APPLICATIONS

Figure 2.28: A simple model of the spacetime geometry of figure 2.27. The particle moves on the whole plane except within the two disks that have been removed. The neck of the wormhole is modeled by the two circles $x(\theta) = \pm d/2 \pm R \cos \theta$, $y(\theta) = R \sin \theta$, $-\pi < \theta \leq \pi$ and has zero length since their points have been identified. There is a given direction in this identification, so that points with the same $\theta$ are the same (you can imagine how this happens by folding the plane across the $y$ axis and then glue the two circles together). The entrance of the particle through one mouth and exit through the other is done as shown for the velocity vector $\vec{v} \rightarrow \vec{v}'$. 
wormhole and study their stability under small perturbations of the initial conditions.

5. Add to the program the option to calculate the distance traveled by the particle. If the particle starts from \((-x_0,0)\) and moves in the \(+x\) direction to the \((x_0,0)\), \(x_0 > R + d/2\) position, draw the trajectory and calculate the distance traveled on paper. Then confirm your calculation from the numerical result coming from your program.

6. Change the boundary conditions, so that the particle bounces off elastically at \(|x| = L/2, |y| = L/2\) and replot all the trajectories mentioned above.

Define the right circle \(c_1\) by the parametric equations

\[
x(\theta) = \frac{d}{2} + R \cos \theta, \quad y(\theta) = R \sin \theta, \quad -\pi < \theta \leq \pi,
\]

and the left circle \(c_2\) by the parametric equations

\[
x(\theta) = -\frac{d}{2} - R \cos \theta, \quad y(\theta) = R \sin \theta, \quad -\pi < \theta \leq \pi.
\]

The particle’s position changes at time \(dt\) by

\[
t_i = idt, \quad x_i = x_{i-1} + v_x dt, \quad y_i = y_{i-1} + v_y dt
\]

for \(i = 1, 2, \ldots\) for given \((x_0,y_0)\), \(t_0 = 0\) and as long as \(t_i \leq t_f\). If the point \((x_i,y_i)\) is outside the boundaries \(|x| = L/2, |y| = L/2\), we redefine \(x_i \rightarrow x_i \pm L, y_i \rightarrow y_i \pm L\) in each case respectively. Points defined by the same value of \(\theta\) are identified, i.e. they represent the same points of space. If the point \((x_i,y_i)\) crosses either one of the circles \(c_1\) or \(c_2\), then we take the particle out from the other circle.

Crossing the circle \(c_1\) is determined by the relation

\[
\left( x_i - \frac{d}{2} \right)^2 + y_i^2 \leq R^2.
\]

The angle \(\theta\) is calculated from the equation

\[
\theta = \tan^{-1} \left( \frac{y_i}{x_i - \frac{d}{2}} \right),
\]
2.4. APPLICATIONS

Figure 2.29: The particle crossing the wormhole through the right circle $c_1$ with velocity $\vec{v}$. It emerges from $c_2$ with velocity $\vec{v}'$. The unit vectors $(\hat{e}_r, \hat{e}_\theta), (\hat{e}'_r, \hat{e}'_\theta)$ are computed from the parametric equations of the two circles $c_1$ and $c_2$.

and the point $(x_i, y_i)$ is mapped to the point $(x'_i, y'_i)$ where

$$ x'_i = -\frac{d}{2} - R \cos \theta, \quad y'_i = y_i, $$

(2.37)

as can be seen in figure 2.29. For mapping $\vec{v} \rightarrow \vec{v}'$, we first calculate the vectors

$$ \begin{align*}
\hat{e}_r &= \cos \theta \hat{x} + \sin \theta \hat{y} \\
\hat{e}_\theta &= -\sin \theta \hat{x} + \cos \theta \hat{y}
\end{align*} 
\rightarrow \begin{align*}
\hat{e}'_r &= -\cos \theta \hat{x} + \sin \theta \hat{y} \\
\hat{e}'_\theta &= \sin \theta \hat{x} + \cos \theta \hat{y}
\end{align*},

(2.38)

so that the velocity

$$ \vec{v} = v_r \hat{e}_r + v_\theta \hat{e}_\theta \rightarrow \vec{v}' = -v_r \hat{e}'_r + v_\theta \hat{e}'_\theta, $$

(2.39)

where the radial components are $v_r = \vec{v} \cdot \hat{e}_r$ and $v_\theta = \vec{v} \cdot \hat{e}_\theta$. Therefore, the relations that give the “emerging” velocity $\vec{v}'$ are:

$$ \begin{align*}
v_r &= v_x \cos \theta + v_y \sin \theta \\
v_\theta &= -v_x \sin \theta + v_y \cos \theta \\
v'_x &= v_r \cos \theta + v_\theta \sin \theta \\
v'_y &= -v_r \sin \theta + v_\theta \cos \theta
\end{align*},

(2.40)

Similarly we calculate the case of entering from $c_2$ and emerging from $c_1$. The condition now is:

$$ \left( x_i + \frac{d}{2} \right)^2 + y_i^2 \leq R^2. $$

(2.41)
The angle $\theta$ is given by
\[ \theta = \pi - \tan^{-1}\left(\frac{y_i}{x_i + \frac{d}{2}}\right), \] (2.42)
and the point $(x_i, y_i)$ is mapped to the point $(x'_i, y'_i)$ where
\[ x'_i = \frac{d}{2} + R \cos \theta, \quad y'_i = y_i. \] (2.43)

For mapping $\vec{v} \to \vec{v}'$, we calculate the vectors
\[ \begin{align*}
\dot{e}_r &= -\cos \theta \dot{x} + \sin \theta \dot{y} \\
\dot{e}_\theta &= \sin \theta \dot{x} + \cos \theta \dot{y}
\end{align*} \to \begin{align*}
\dot{e}'_r &= \cos \theta \dot{x} + \sin \theta \dot{y} \\
\dot{e}'_\theta &= -\sin \theta \dot{x} + \cos \theta \dot{y},
\end{align*} \] (2.44)
so that the velocity
\[ \vec{v} = v_r \dot{e}_r + v_\theta \dot{e}_\theta \to \vec{v}' = -v_r \dot{e}'_r + v_\theta \dot{e}'_\theta. \] (2.45)

The emerging velocity $\vec{v}'$ is:
\[ \begin{align*}
v_r &= -v_x \cos \theta + v_y \sin \theta \\
v_\theta &= v_x \sin \theta + v_y \cos \theta \\
v'_r &= -v_r \cos \theta - v_\theta \sin \theta \\
v'_\theta &= -v_r \sin \theta + v_\theta \cos \theta.
\end{align*} \] (2.46)

Systematic errors are now coming from crossing the two mouths of the wormhole. There are no systematic errors from crossing the boundaries $|x| = L/2, |y| = L/2$ (why?). Try to think of ways to control those errors and study them.

The closed trajectories that we are looking for come from the initial conditions
\[ (x_0, y_0, v_0, \phi) = (0, 0, 1, 0) \] (2.47)
and they connect points 1 of figure 2.28. They are unstable, as can be seen by taking $\phi \to \phi + \epsilon$.

The closed trajectories that cross the wormhole and “wind” through space can come from the initial conditions
\[ \begin{align*}
(x_0, y_0, v_0, \phi) &= (-9, 0, 1, 0) \\
(x_0, y_0, v_0, \phi) &= (2.5, -3, 1, 90^\circ)
\end{align*} \]
and cross the points 3 → 3 and 2 → 2 → 4 → 4 respectively. They are also unstable, as can be easily verified by using the program that you will write. The full program is listed below:

```

It is easy to compile and run the program. See also the files Wormhole.csh and Wormhole_animate.gnu of the accompanying software and run the gnuplot commands:

```
gnuplot> file = "Wormhole.dat"
gnuplot> R=1; d=5; L=20;
gnuplot> ! ./Wormhole.csh
gnuplot> t0=0; dt=0.2; load "Wormhole_animate.gnu"
```

You are now ready to answer the rest of the questions that we asked in our list.
2.5 Problems

2.1 Change the program Circle.f90 so that it prints the number of full circles traversed by the particle.

2.2 Add all the necessary tests on the parameters entered by the user in the program Circle.f90, so that the program is certain to run without problems. Do the same for the rest of the programs given in the same section.

2.3 A particle moves with constant angular velocity $\omega$ on a circle that has the origin of the coordinate system at its center. At time $t_0 = 0$, the particle is at $(x_0, y_0)$. Write the program CircularMotion.f90 that will calculate the particle's trajectory. The user should enter the parameters $\omega, x_0, y_0, t_0, t_f, \Delta t$. The program should print the results like the program Circle.f90 does.

2.4 Change the program SimplePendulum.f90 so that the user could enter a non zero initial velocity.

2.5 Study the $k \to 0$ limit in the projectile motion given by equations (2.10). Expand $e^{-kt} = 1 - kt + \frac{1}{2!} (kt)^2 + \ldots$ and keep the non vanishing terms as $k \to 0$. Then keep the next order leading terms which have a smaller power of $k$. Program these relations in a file ProjectileSmallAirResistance.f90. Consider the initial conditions $\vec{v}_0 = \hat{x} + \hat{y}$ and calculate the range of the trajectory numerically by using the two programs ProjectileSmallAirResistance.f90, ProjectileAirResistance.f90. Determine the range of values of $k$ for which the two results agree within 5% accuracy.

2.6 Write a program for a projectile which moves through a fluid with fluid resistance proportional to the square of the velocity. Compare the range of the trajectory with the one calculated by the program ProjectileAirResistance.f90 for the parameters shown in figure 2.10.

2.7 Change the program Lissajous.f90 so that the user can enter a different amplitude and initial phase in each direction. Study the case where the amplitudes are the same and the phase difference in the two directions are $\pi/4, \pi/2, \pi, -\pi$. Repeat by taking the amplitude in the $y$ direction to be twice as much the amplitude in the $x$ direction.
2.8 Change the program ProjectileAirResistance.f90, so that it can calculate also the $k = 0$ case.

2.9 Change the program ProjectileAirResistance.f90 so that it can calculate the trajectory of the particle in three dimensional space. Plot the position coordinates and the velocity components as a function of time. Plot the three dimensional trajectory using `splot` in gnuplot and animate the trajectory using the gnuplot script `animate3D.gnu`.

2.10 Change the program ChargeInB.f90 so that it can calculate the number of full revolutions that the projected particle’s position on the $x-y$ plane makes during its motion.

2.11 Change the program box1D_1.f90 so that it prints the number of the particle’s collisions on the left wall, on the right wall and the total number of collisions to the `stdout`.

2.12 Do the same for the program box1D_2.f90. Fill the table on page 115 the number of calculated collisions and comment on the results.

2.13 Run the program box1D_1.f90 and choose $L = 10$, $v_0=1$. Decrease the step $\Delta t$ up to the point that the particle stops to move. For which value of $\Delta t$ this happens? Increase $v_0=10, 100$. Until which value of $\Delta t$ the particle moves now? Why?

2.14 Change the REAL declarations to REAL(8) in the program box1D_1.f90. Add explicit exponents D0 to all constants (e.g. $0.0D0$). Compare your results to those obtained in section 2.3.2. Repeat problem 2.13. What do you observe?

2.15 Change the program box1D_1.f90 so that you can study non elastic collisions $v'_y = -ev$, $0 < e \leq 1$ with the walls.

2.16 Change the program box2D_1.f90 so that you can study inelastic collisions with the walls, such that $v'_x = -ev_x$, $v'_y = -ev_y$, $0 < e \leq 1$.

2.17 Use the method of calculating time in the programs box1D_4.f90 and box1D_5.f90 in order to produce the results in figure 2.21.

2.18 Particle falls freely moving in the vertical direction. It starts with zero velocity at height $h$. Upon reaching the ground, it bounces inelastically such that $v'_y = -ev_y$ with $0 < e \leq 1$ a parameter. Write the necessary program in order to study numerically the particle’s motion and study the cases $e = 0.1, 0.5, 0.9, 1.0$. 
2.19 Generalize the program of the previous problem so that you can study the case $\vec{v}_0 = v_0 \hat{x}$. Animate the calculated trajectories.

2.20 Study the motion of a particle moving inside the box of figure 2.30. Count the number of collisions of the particle with the walls before it leaves the box.

![Figure 2.30: Problem 2.20](image)

2.21 Study the motion of the point particle on the “billiard table” of figure 2.31. Count the number of collisions with the walls before the particle enters into a hole. The program should print from which hole the particle left the table.

![Figure 2.31: Problem 2.21](image)

2.22 Write a program in order to study the motion of a particle in the box of figure 2.32. At the center of the box there is a disk on which the particle bounces off elastically (Hint: use the routine reflectVonCircle of the program Cylinder3D.f90).

2.23 In the box of the previous problem, put four disks on which the particle bounces of elastically like in figure 2.33.
2.24 Consider the arrangement of figure 2.34. Each time the particle bounces elastically off a circle, the circle disappears. The game is over successfully if all the circles vanish. Each time the particle bounces off on the wall to the left, you lose a point. Try to find trajectories that minimize the number of lost points.
Chapter 3
Logistic Map

Nonlinear differential equations model interesting dynamical systems in physics, biology and other branches of science. In this chapter we perform a numerical study of the discrete logistic map as a “simple mathematical model with complex dynamical properties” [21] similar to the ones encountered in more complicated and interesting dynamical systems. For certain values of the parameter of the map, one finds chaotic behavior giving us an opportunity to touch on this very interesting topic with important consequences in physical phenomena. Chaotic evolution restricts our ability for useful predictions in an otherwise fully deterministic dynamical system: measurements using slightly different initial conditions result in a distribution which is indistinguishable from the distribution coming from sampling a random process. This scientific field is huge and active and we refer the reader to the bibliography for a more complete introduction [21, 22, 23, 24, 25, 26, 27, 28]..

3.1 Introduction

The most celebrated application of the logistic map comes from the study of population growth in biology. One considers populations which reproduce at fixed time intervals and whose generations do not overlap.

The simplest (and most naive) model is the one that makes the reasonable assumption that the rate of population growth \( \frac{dP(t)}{dt} \) of a population \( P(t) \) is proportional to the current population:

\[
\frac{dP(t)}{dt} = kP(t).
\]

(3.1)

The general solution of the above equation is \( P(t) = P(0)e^{kt} \) showing an exponential population growth for \( k > 0 \) an decline for \( k < 0 \). It
is obvious that this model is reasonable as long as the population is small enough so that the interaction with its environment (adequate food, diseases, predators etc) can be neglected. The simplest model that takes into account some of the factors of the interaction with the environment (e.g. starvation) is obtained by the introduction of a simple non linear term in the equation so that

\[
\frac{dP(t)}{dt} = kP(t)(1 - bP(t)).
\] (3.2)

The parameter \(k\) gives the maximum growth rate of the population and \(b\) controls the ability of the species to maintain a certain population level. The equation (3.2) can be discretized in time by assuming that each generation reproduces every \(\delta t\) and that the \(n\)-th generation has population \(P_n = P(t_n)\) where \(t_n = t_0 + (n - 1)\delta t\). Then \(P(t_{n+1}) \approx P(t_n) + \delta tP'(t_n)\) and equation (3.1) becomes

\[
P_{n+1} = r P_n,
\] (3.3)

where \(r = 1 + k\delta t\). The solutions of the above equation are well approximated by \(P_n \sim P_0 e^{kt_n} \propto e^{(r-1)n}\) so that we have population growth when \(r > 1\) and decline when \(r < 1\). Equation (3.2) can be discretized as follows:

\[
P_{n+1} = P_n(r - bP_n).
\] (3.4)

Defining \(x_n = (b/r)P_n\) we obtain the logistic map

\[
x_{n+1} = rx_n(1 - x_n).
\] (3.5)

We define the functions

\[
f(x) = rx(1 - x), \quad F(x, r) = rx(1 - x)
\] (3.6)

(whose only difference is that, in the first one, \(r\) is considered as a given parameter), so that

\[
x_{n+1} = f(x_n) = f^{(2)}(x_{n-1}) = \ldots = f^{(n)}(x_1) = f^{(n+1)}(x_0),
\] (3.7)

where we use the notation \(f^{(1)}(x) = f(x), f^{(2)}(x) = f(f(x)), f^{(3)}(x) = f(f(f(x))), \ldots\) for function composition. In what follows, the derivative of \(f\) will be useful:

\[
f'(x) = \frac{\partial F(x, r)}{\partial x} = r(1 - 2x).
\] (3.8)
Since we interpret \( x_n \) to be the fraction of the population with respect to its maximum value, we should have \( 0 \leq x_n \leq 1 \) for each \( n \). The function \( f(x) \) has one global maximum for \( x = 1/2 \) which is equal to \( f(1/2) = r/4 \). Therefore, if \( r > 4 \), then \( f(1/2) > 1 \), which for an appropriate choice of \( x_0 \) will lead to \( x_{n+1} = f(x_n) > 1 \) for some value of \( n \). Therefore, the interval of values of \( r \) which is of interest for our model is

\[
0 < r \leq 4 .
\] (3.9)

The logistic map (3.5) may be viewed as a finite difference equation and it is a one step inductive relation. Given an initial value \( x_0 \), a sequence of values \( \{x_0, x_1, \ldots, x_n, \ldots\} \) is produced. This will be referred to as the trajectory of \( x_0 \). In the following sections we will study the properties of these trajectories as a function of the parameter \( r \).

The solutions of the logistic map are not known except in special cases. For \( r = 2 \) we have

\[
x_n = \frac{1}{2} \left( 1 - (1 - x_0)^{2^n} \right) ,
\] (3.10)

and for \( r = 4 \)

\[
x_n = \sin^2(2^n \pi \theta) , \quad \theta = \frac{1}{\pi} \sin^{-1} \sqrt{x_0} .
\] (3.11)

For \( r = 2 \), \( \lim_{n \to \infty} x_n = 1/2 \) whereas for \( r = 4 \) we have periodic trajectories resulting in rational \( \theta \) and non periodic resulting in irrational \( \theta \). For other values of \( r \) we have to resort to a numerical computation of the trajectories of the logistic map.

### 3.2 Fixed Points and \( 2^n \) Cycles

It is obvious that if the point \( x^* \) is a solution of the equation \( x = f(x) \), then \( x_n = x^* \Rightarrow x_{n+k} = x^* \) for every \( k \geq 0 \). For the function \( f(x) = rx(1 - x) \) we have two solutions

\[
x^*_1 = 0 \quad \text{and} \quad x^*_2 = 1 - 1/r .
\] (3.12)

¹Note that if \( x_n > 1 \) then \( x_{n+1} < 0 \), so that if we want \( x_n \geq 0 \) for each \( n \), then we should have \( x_n \leq 1 \) for each \( n \).

²In the bibliography, the term “splinter of \( x_0 \)” is frequently used.

We will see that for appropriate values of $r$, these solutions are *attractors* of most of the trajectories. This means that for a range of values for the initial point $0 \leq x_0 \leq 1$, the sequence $\{x_n\}$ approaches asymptotically one of these points as $n \to \infty$. Obviously the (measure zero) sets of initial values $\{x_0\} = \{x^*_1\}$ and $\{x_0\} = \{x^*_2\}$ result in trajectories attracted by $x^*_1$ and $x^*_2$ respectively. In order to determine which one of the two values is preferred, we need to study the *stability* of the fixed points $x^*_1$ and $x^*_2$. For this, assume that for some value of $n$, $x_n$ is infinitesimally close to the fixed point $x^*$ so that

$$
x_n = x^* + \epsilon_n \quad \text{and} \quad x_{n+1} = x^* + \epsilon_{n+1}. \tag{3.13}
$$

Since

$$
x_{n+1} = f(x_n) = f(x^* + \epsilon_n) \approx f(x^*) + \epsilon_n f'(x^*) = x^* + \epsilon_n f'(x^*), \tag{3.14}
$$

where we used the Taylor expansion of the analytic function $f(x^* + \epsilon_n)$ about $x^*$ and the relation $x^* = f(x^*)$, we have that $\epsilon_{n+1} = \epsilon_n f'(x^*)$. Then we obtain

$$
\left| \frac{\epsilon_{n+1}}{\epsilon_n} \right| = |f'(x^*)|. \tag{3.15}
$$

Therefore, if $|f'(x^*)| < 1$ we obtain $\lim_{n \to \infty} \epsilon_n = 0$ and the fixed point $x^*$ is *stable*: the sequence $\{x_{n+k}\}$ approaches $x^*$ asymptotically. If $|f'(x^*)| > 1$ then the sequence $\{x_{n+k}\}$ deviates away from $x^*$ and the fixed point is *unstable*. The limiting case $|f'(x^*)| = 1$ should be studied separately and it indicates a change in the stability properties of the fixed point. In the following discussion, these points will be shown to be bifurcation points.

For the function $f(x) = rx(1-x)$ with $f'(x) = r(1-2x)$ we have that $f'(0) = r$ and $f'(1-1/r) = 2 - r$. Therefore, if $r < 1$ the point $x^*_1 = 0$ is an attractor, whereas the point $x^*_2 = 1 - 1/r < 0$ is irrelevant. When $r > 1$, the point $x^*_1 = 0$ results in $|f'(x^*_1)| = r > 1$, therefore $x^*_1$ is unstable. Any initial value $x_0$ near $x^*_1$ deviates from it. Since for $1 < r < 3$ we have that $0 \leq |f'(x^*_2)| = |2 - r| < 1$, the point $x^*_2$ is an attractor. Any initial value $x_0 \in (0, 1)$ approaches $x^*_2 = 1 - 1/r$. When $r = r^{(1)}_c = 1$ we have the limiting case $x^*_1 = x^*_2 = 0$ and we say that at the critical value $r^{(1)}_c = 1$ the fixed point $x^*_1$ bifurcates to the two fixed points $x^*_1$ and $x^*_2$.

As $r$ increases, the fixed points continue to bifurcate. Indeed, when $r = r^{(2)}_c = 3$ we have that $f'(x^*_2) = 2 - r = -1$ and for $r > r^{(2)}_c$ the point $x^*_2$ becomes unstable. Consider the solution of the equation $x = f^{(2)}(x)$. If $0 < x^* < 1$ is one of its solutions and for some $n$ we have that $x_n = x^*$,
then \( x_{n+2} = x_{n+4} = \ldots = x_{n+2k} = \ldots = x^* \) and \( x_{n+1} = x_{n+3} = \ldots = x_{n+2k+1} = \ldots = f(x^*) \) (therefore \( f(x^*) \) is also a solution). If \( 0 < x^*_3 < x^*_4 < 1 \) are two such different solutions with \( x^*_3 = f(x^*_4) \), then the trajectory is periodic with period 2. The points \( x^*_3, x^*_4 \) are such that they are real solutions of the equation

\[
f^{(2)}(x) = r^2 x(1-x)(1-rx(1-x)) = x, \quad \text{(3.16)}
\]

and at the same time they are not the solutions \( x^*_1 = 0 \), \( x^*_2 = 1 - 1/r \) of the equation \( x = f^{(2)}(x) \), the polynomial above can be written in the form (see [22] for more details)

\[
x \left( x - \left( \frac{1}{r} \right) \right) (Ax^2 + Bx + C) = 0. \quad \text{(3.17)}
\]

By expanding the polynomials (3.16), (3.17) and comparing their coefficients we conclude that \( A = -r^3, B = r^2(r + 1) \) and \( C = -r(r + 1) \). The roots of the trinomial in (3.17) are determined by the discriminant \( \Delta = r^2(r + 1)(r - 3) \). For the values of \( r \) of interest (\( 1 < r \leq 4 \)), the discriminant becomes positive when \( r > r^{(2)}_c = 3 \) and we have two different solutions

\[
x^*_\alpha = (\frac{1}{r} \pm \sqrt{r^2 - 2r - 3})/(2r) \quad \alpha = 3, 4. \quad \text{(3.18)}
\]

When \( r = r^{(2)}_c \) we have one double root, therefore a unique fixed point.

The study of the stability of the solutions of \( x = f^{(2)}(x) \) requires the same steps that led to the equation (3.15) and we determine if the absolute value of \( f^{(2)}(x) \) is greater, less or equal to one. By noting that \( f^{(2)}(x_3) = f'(x_3)f(x_3) = f'(x_4)f(x_4) = -r^2 + 2r + 4 \), we see that for \( r = r^{(3)}_c = 3 \), \( f^{(2)}(x^*_3) = f^{(2)}(x^*_4) = 1 \) and for \( r = r^{(3)}_c = 1 + \sqrt{6} \approx 3.4495 \), \( f^{(2)}(x_3) = f^{(2)}(x_4) = -1 \). For the intermediate values \( 3 < r < 1 + \sqrt{6} \) the derivatives \( |f^{(2)}(x^*_\alpha)| < 1 \) for \( \alpha = 3, 4 \). Therefore, these points are stable solutions of \( x = f^{(2)}(x) \) and the points \( x^*_1, x^*_2 \) bifurcate to \( x^*_\alpha, \alpha = 1, 2, 3, 4 \) for \( r = r^{(2)}_c = 3 \). Almost all trajectories with initial points in the interval [0, 1] are attracted by the periodic trajectory with period 2, the “2-cycle” \( \{x^*_3, x^*_4\} \).

\(^*\)Because, if \( x^* = f(x^*) \Rightarrow f^{(2)}(x^*) = f(f(x^*)) = f(x^*) = x^* \) etc., the point \( x^* \) is also a solution of \( x^* = f^{(2)}(x^*) \).

\(^b\)The chain rule \( dh(g(x))/dx = h'(g(x))g'(x) \) gives that \( f^{(2)}(x^*_1) = df(f(x^*_1))/dx = f'(f(x^*_1))f'(x^*_1) = f'(x^*_1)f'(x^*_1) \) and similarly for \( f^{(2)}(x^*_1) \). We can prove by induction that for the \( n \) solutions \( x^*_{n+1}, x^*_{n+2}, \ldots, x^*_{2n} \) that belong to the \( n \)-cycle of the equation \( x = f^{(n)}(x) \) we have that \( f^{(n)}(x_{n+i}) = f'(x_{n+i})f'(x_{n+i+1}) \ldots f'(x_{2n}) \) for every \( i = 1, \ldots, n \).
Using similar arguments we find that the fixed points \( x^*_\alpha, \alpha = 1, 2, 3, 4 \) bifurcate to the eight fixed points \( x^*_\alpha, \alpha = 1, \ldots, 8 \) when \( r = r_c^{(3)} = 1 + \sqrt{6} \). These are real solutions of the equation that gives the 4-cycle \( x = f^{(4)}(x) \).

For \( r_c^{(3)} < r < r_c^{(4)} \approx 3.5441 \), the points \( x^*_\alpha, \alpha = 5, \ldots, 8 \) are a stable 4-cycle which is an attractor of almost all trajectories of the logistic map\(^6\). Similarly, for \( r_c^{(4)} < r < r_c^{(5)} \) the 16 fixed points of the equation \( x = f^{(8)}(x) \) give a stable 8-cycle, for \( r_c^{(5)} < r < r_c^{(6)} \) a stable 16-cycle etc\(^7\). This is the phenomenon which is called period doubling which continues ad infinitum. The points \( r_c^{(n)} \) are getting closer to each other as \( n \) increases so that \( \lim_{n \to \infty} r_c^{(n)} = r_c \approx 3.56994567 \). As we will see, \( r_c \) marks the onset of the non-periodic, chaotic behavior of the trajectories of the logistic map.

\[\begin{align*}
\text{Computing the bifurcation points becomes quickly intractable and we} \\
\text{have to resort to a numerical computation of their values. Initially we} \\
\text{will write a program that computes trajectories of the logistic map for chosen} \\
\text{values of} \ r \ \text{and} \ x_0. \ \text{The program can be found in the file} \ \text{logistic.f90} \\
\text{and is listed below:}
\end{align*}\]

\[\begin{align*}
\text{The points} \ x^*_\alpha, \ \alpha = 1, \ldots, 4 \ \text{are unstable fixed points and 2-cycle.} \\
\text{Generally, for} \ r_c^{(n)} < r < r_c^{(n+1)} < r_c \approx 3.56994567 \ \text{we have} \ 2^n \ \text{fixed points of} \ \text{the equation} \ x = f^{(2n-1)}(x) \ \text{and stable} \ 2^{n-1}\text{-cycles, which are attractors of almost all trajectories.}
\end{align*}\]
3.2. FIXED POINTS AND $2^n$ CYCLES

The program is compiled and run using the commands:

```
> gfortran logistic.f90 -o l
> echo "100 0.5 0.1" | ./l
```

The command echo prints to the stdout the values of the parameters NSTEPS=100, $r=0.5$ and $x_0=0.1$. Its stdout is redirected to the stdin of the command ./l by using a pipe via the symbol |, from which the program reads their value and uses them in the calculation. The results can be found in two columns in the file log.dat and can be plotted using gnuplot. The plots are put in figure 3.1 and we can see the first two bifurcations when $r$ goes past the values $r_c^{(1)}$ and $r_c^{(2)}$. Similarly, we can study trajectories which are $2^n$-cycles when $r$ crosses the values $r_c^{(n-1)}$.

Another way to depict the 2-cycles is by constructing the cobweb plots: We start from the point $(x_0,0)$ and we calculate the point $(x_0,x_1)$, where $x_1 = f(x_0)$. This point belongs on the curve $y = f(x)$. The point $(x_0,x_1)$ is then projected on the diagonal $y=x$ and we obtain the point $(x_1,x_1)$. We repeat $n$ times obtaining the points $(x_n,x_{n+1})$ and $(x_{n+1},x_{n+1})$ on $y = f(x)$.
152

CHAPTER 3. LOGISTIC MAP

Figure 3.2: Cobweb plots of the logistic map for \( r = 2.8 \) and \( 3.3 \). (Left) The left plot is an example of a fixed point \( x^* = f(x^*) \). The green line is \( y = f(x) \) and the blue line is \( y = f^{(2)}(x) \). The trajectory ends at the unique non zero intersection of the diagonal and \( y = f(x) \) which is \( x^*_1 = 1 - 1/r \). The trajectory intersects the curve \( y = f^{(2)}(x) \) at the same point. \( y = f^{(2)}(x) \) does not intersect the diagonal anywhere else. (Right) The right plot shows an example of a 2-cycle. \( y = f^{(2)}(x) \) intersects the diagonal at two additional points determined by \( x^*_3 \) and \( x^*_4 \). The trajectory ends up on the orthogonal \( (x^*_3, x^*_3), (x^*_4, x^*_3), (x^*_3, x^*_4), (x^*_3, x^*_4) \).

and \( y = x \) respectively. The fixed points \( x^* = f(x^*) \) are at the intersections of these curves and, if they are attractors, the trajectories will converge on them. If we have a \( 2^n \)-cycle, we will observe a periodic trajectory going through points which are solutions to the equation \( x = f^{(2^n)}(x) \). This exercise can be done by using the following program, which can be found in the file logistic1.f90:

```fortran
program logistic_map
  implicit none
  integer :: NSTEPS, i
  real(8) :: r, x0, x1
  ! Input:
  print *, '# Enter NSTEPS, r, x0:'
  read *, NSTEPS, r, x0
  print *, '# NSTEPS = ', NSTEPS
  print *, '# r = ', r
  print *, '# x0 = ', x0
  ! Initialize:
  open(unit=33, file='trj.dat')
  ! Calculate:
```
3.2. FIXED POINTS AND $2^N$ CYCLES

Figure 3.3: (Left) A 4-cycle for $r = 3.5$. The blue curve is $y = f^{(4)}(x)$ which intersects the diagonal at four points determined by $x_0, a = 5, 6, 7, 8$. The four cycle passes through these points. (Right) a non periodic orbit for $r = 3.7$ when the system exhibits chaotic behavior.

```fortran
write(33,*) 0, x0,0
do i=1,NSTEPS
  x1 = r * x0 * (1.0D0-x0)
  write(33,*) 2*i-3,x0, x1
  write(33,*) 2*i-2,x1, x1
  x0 = x1
enddo
close(33)
end program logistic_map
```

Compiling and running this program is done exactly as in the case of the program in logistic.f90. We can plot the results using gnuplot. The plot in figure 3.2 can be constructed using the commands:

```
gnuplot> set size square
gnuplot> f(x) = r*x*(1.0-x)
gnuplot> r = 3.3
gnuplot> plot "<echo 50 3.3 0.2l/1;cat trj.dat" using 2:3 w l
gnuplot> replot f(x) .f(f(x)).x
```

The plot command shown above, runs the program exactly as it is done on the command line. This is accomplished by using the symbol <, which reads the plot from the stdout of the command "echo 50 3.3 0.2l/1;cat trj.dat". Only the second command "echo trj.dat" writes to the stdout, therefore the plot is constructed from the contents of the file trj.dat. The following line adds the plots of the functions $f(x)$, $f^{(2)}(x) = f(f(x))$ and of the diagonal $y = x$. Figures 3.2 and 3.3 show examples of attractors which are fixed points, 2-cycles and 4-cycles. An
example of a non periodic trajectory is also shown, which exhibits chaotic behavior which can happen when \( r > r_c \approx 3.56994567 \).

### 3.3 Bifurcation Diagrams

The bifurcations of the fixed points of the logistic map discussed in the previous section can be conveniently shown on the “bifurcation diagram”. We remind to the reader that the first bifurcations happen at the critical values of \( r \)

\[
\begin{align*}
r_c^{(1)} &< r_c^{(2)} < r_c^{(3)} < \ldots < r_c^{(n)} < \ldots < r_c,
\end{align*}
\]

(3.19)

where \( r_c^{(1)} = 1, r_c^{(2)} = 3, r_c^{(3)} = 1 + \sqrt{6} \) and \( r_c = \lim_{n \to \infty} r_c^{(n)} \approx 3.56994567 \). For \( r_c^{(n)} < r < r_c^{(n+1)} \) we have \( 2^n \) fixed points \( x_\alpha^*(r), \alpha = 1, 2, \ldots, 2^n \) of \( x = f^{(2^n)}(x) \). By plotting these points \( x_\alpha^*(r) \) as a function of \( r \) we construct the bifurcation diagram. These can be calculated numerically by using the program bifurcate.f90. In this program, the user selects the values of \( r \) that she needs to study and for each one of them the program records the point of the \( 2^{n-1} \)-cycles \( x_\alpha^*(r), \alpha = 2^{n-1} + 1, 2^{n-1} + 2, \ldots, 2^n \). This is easily done by computing the logistic map several times until we are sure that the trajectories reach the stable state. The parameter \( NTRANS \) in the program determines the number of points that we throw away, which should contain all the transient behavior. After \( NTRANS \) steps, the program records \( NSTEPS \) points, where \( NSTEPS \) should be large enough to cover all the points of the \( 2^{n-1} \)-cycles or depict a dense enough set of values of the non periodic orbits. The program is listed below:

```fortran
program bifurcation_diagram
  implicit none
  real(8) , parameter :: rmin = 2.5D0
  real(8) , parameter :: rmax = 4.0D0
  integer , parameter :: NTRANS = 500 !Number of discarded steps
  integer , parameter :: NSTEPS = 100 !Number of recorded steps
  integer , parameter :: NSTEPS = 2000 !Number of values of r
  integer :: i
  real(8) :: r, dr, x0, x1

  ! Initialize:
```

If we want to be more precise, the bifurcation diagram contains also the unstable points. What we really construct is the orbit diagram which contains only the stable points.
3.3. BIFURCATION DIAGRAMS

```
open(unit=33, file='bif.dat')
dr = (rmax-rmin)/RSTEPS ! Increment in r
! --- Calculate:
r = rmin
do while (r .le. rmax)
x0 = 0.5D0
! --- Transient steps: skip
   do i=1,NTRANS
      x1 = r * x0 * (1.0D0-x0)
      x0 = x1
   enddo
   do i=1,NSTEPS
      x1 = r * x0 * (1.0D0-x0)
      write(33,*)(r,x1)
      x0 = x1
   enddo
   r = r + dr
enddo ! do while
close(33)
end program bifurcation_diagram
```

Figure 3.4: (Left) The bifurcation diagram computed by the program `bifurcate.f90` for $2.5 < r < 4$. Notice the first bifurcation points followed by intervals of chaotic, non-periodic orbits interrupted by intermissions of stable periodic trajectories. The chaotic trajectories take values in subsets of the interval $(0,1)$. For $r = 4$ they take values within the whole $(0,1)$. One can see that for $r = 1 + \sqrt{8} \approx 3.8284$ we obtain a 3-cycle which subsequently bifurcates to $3 \cdot 2^n$-cycles. (Right) The diagram on the left is magnified in a range of $r$ showing the self-similarity of the diagram at all scales.

The program can be compiled and run using the commands:

```
> gfortran bifurcate.f90 -o b
> ./b;
```
The left plot of figure 3.4 can be constructed by the gnuplot commands:

```
gnuplot> plot "bif.dat" with dots
```

We observe the fixed points and the $2^n$-cycles for $r < r_c$. When $r$ goes past $r_c$, the trajectories become non-periodic and exhibit chaotic behavior. Chaotic behavior will be discussed more extensively in the next section. For the time being, we note that if we measure the distance between the points $\Delta r^{(n)} = r^{(n+1)}_c - r^{(n)}_c$, we find that it decreases constantly with $n$ so that

$$\lim_{n \to \infty} \frac{\Delta r^{(n)}}{\Delta r^{(n+1)}} = \delta \approx 4.669 \, 201 \, 609$$

where $\delta$ is the Feigenbaum constant. An additional constant $\alpha$, defined by the quotient of the separation of adjacent elements $\Delta w_n$ of period doubled attractors from one double to the next $\Delta w_{n+1}$, is

$$\lim_{n \to \infty} \frac{\Delta w_n}{\Delta w_{n+1}} = \alpha \approx 2.502 \, 907 \, 875$$

It is also interesting to note the appearance of a 3-cycle right after $r = 1 + \sqrt{8} \approx 3.8284 > r_c$. By using the theorem of Sharkovskii, Li and Yorke showed that any one dimensional system has 3-cycles, therefore it will have cycles of any length and chaotic trajectories. The stability of the 3-cycle can be studied from the solutions of $x = f^3(x)$ in exactly the same way that we did in equations (3.16) and (3.17) (see [22] for details). Figure 3.5 magnifies a branch of the 3-cycle. By magnifying different regions in the bifurcation plot, as shown in the right plot of figure 3.4, we find similar shapes to the branching of the 3-cycle. Figure 3.4 shows that between intervals of chaotic behavior we obtain “windows” of periodic trajectories. These are infinite but countable. It is also quite interesting to note that if we magnify a branch withing these windows, we obtain a diagram that is similar to the whole diagram! We say that the bifurcation diagram exhibits self similarity. There are more interesting properties of the bifurcation diagram and we refer the reader to the bibliography for a more complete exposition.

We close this section by mentioning that the qualitative properties of the bifurcation diagram are the same for a whole class of functions. Feigenbaum discovered that if one takes any function that is concave and

---

Figure 3.5: Magnification of one of the three branches of the 3-cycle for $r > 1 + \sqrt{8}$. To the left, we observe the temporary halt of the chaotic behavior of the trajectory, which comes back as shown in the plot to the right after an intermission of stable periodic trajectories.

has a unique global maximum, its bifurcation diagram behaves qualitatively the same way as that of the logistic map. Examples of such functions studied in the literature are $g(x) = xe^{r(1-x)}$, $u(x) = r \sin(\pi x)$ and $w(x) = b - x^2$. The constants $\delta$ and $\alpha$ of equations (3.20) and (3.21) are the same of all these mappings. The functions that result in chaotic behavior are studied extensively in the literature and you can find a list of those in [28].

3.4 The Newton-Raphson Method

In order to determine the bifurcation points, one has to solve the nonlinear, polynomial, algebraic equations $x = f^{(n)}(x)$ and $f^{(n)'}(x) = -1$. For this reason, one has to use an approximate numerical calculation of the roots, and the simple Newton-Raphson method will prove to be a good choice.

Newton-Raphson’s method uses an initial guess $x_0$ for the solution of the equation $g(x) = 0$ and computes a sequence of points $x_1, x_2, \ldots, x_n, x_{n+1}, \ldots$ that presumably converges to one of the roots of the equation. The computation stops at a finite $n$, when we decide that the desired level of accuracy has been achieved. In order to understand how it works, we assume that $g(x)$ is an analytic function for all the values of $x$ used in

$^{10}$ The function $x \exp(r(1-x))$ has been used as a model for populations whose large density is restricted by epidemics. The populations are always positive independently of the (positive) initial conditions and the value of $r$. 
the computation. Then, by Taylor expanding around \( x_n \) we obtain
\[
g(x_{n+1}) = g(x_n) + (x_{n+1} - x_n)g'(x) + \ldots
\] (3.22)

If we wish to have \( g(x_{n+1}) \approx 0 \), we choose
\[
x_{n+1} = x_n - \frac{g(x_n)}{g'(x_n)}.
\] (3.23)

The equation above gives the Newton-Raphson method for one equation \( g(x) = 0 \) of one variable \( x \). Different choices for \( x_0 \) will possibly lead to different roots. When \( g'(x), g''(x) \) are non zero at the root and \( g'''(x) \) is bounded, the convergence of the method is quadratic with the number of iterations. This means that there is a neighborhood of the root \( \alpha \) such that the distance \( \Delta x_{n+1} = x_{n+1} - \alpha \) is \( \Delta x_{n+1} \propto (\Delta x_n)^2 \). If the root \( \alpha \) has multiplicity larger than 1, convergence is slower. The proofs of these statements are simple and can be found in [29].

The Newton-Raphson method is simple to program and, most of the times, sufficient for the solution of many problems. In the general case it works well only close enough to a root. We should also keep in mind that there are simple reasons for the method to fail. For example, when \( g'(x_n) = 0 \) for some \( n \), the method stops. For functions that tend to 0 as \( x \to \pm\infty \), it is easy to make a bad choice for \( x_0 \) that does not lead to convergence to a root. Sometimes it is a good idea to combine the Newton-Raphson method with the bisection method. When the derivative \( g'(x) \) diverges at the root we might get into trouble. For example, the equation \( |x|^\nu = 0 \) with \( 0 < \nu < 1/2 \), does not lead to a convergent sequence. In some cases, we might enter into non-convergent cycles [8]. For some functions the basin of attraction of a root (the values of \( x_0 \) that will converge to the root) can be tiny. See problem 13.

As a test case of our program, consider the equation
\[
\epsilon \tan \epsilon = \sqrt{\rho^2 - \epsilon^2}
\] (3.24)

which results from the solution of Schrödinger’s equation for the energy spectrum of a quantum mechanical particle of mass \( m \) in a one dimensional potential well of depth \( V_0 \) and width \( L \). The parameters \( \epsilon = \sqrt{mL^2E/(2\hbar)} \) and \( \rho = \sqrt{mL^2V_0/(2\hbar)} \). Given \( \rho \), we solve for \( \epsilon \) which gives the energy \( E \). The function \( g(x) \) and its derivative \( g'(x) \) are
\[
g(x) = x \tan x - \sqrt{\rho^2 - x^2}
g'(x) = \frac{x}{\sqrt{\rho^2 - x^2}} + \frac{x}{\cos^2 x} + \tan x.
\] (3.25)
3.4. THE NEWTON-RAPHSON METHOD

The program of the Newton-Raphson method for solving the equation $g(x) = 0$ can be found in the file nr.f90:

```fortran
program NewtonRaphson
implicit none
real(8), parameter :: rho = 15.0D0
real(8), parameter :: eps = 1D-6
integer, parameter :: NMAX = 1000
real :: x0, x1, err, g, gp
integer :: i
print *, 'Enter x0: '
read *, x0
err = 1.0D0
print *, 'iter', 'x', 'error'
p
print *, 0, x0, err
do i = 1, NMAX
!value of function g(x):
  g = x0*tan(x0) - sqrt(rho*rho - x0*x0)
!value of the derivative g'(x):
  gp = (x0/sqrt(rho*rho - x0*x0)) + x0/(cos(x0)**2) + tan(x0)
  x1 = x0 - g/gp
  err = abs(x1 - x0)
p
if(err .lt. eps) exit
  x0 = x1
endo
end program NewtonRaphson
```

In the program listed above, the user is asked to set the initial point $x_0$. We fix $\rho = \rho_0 = 15$. It is instructive to make the plot of the left and right hand sides of (3.24) and make a graphical determination of the roots from their intersections. Then we can make appropriate choices of the initial point $x_0$. Using gnuplot, the plots are made with the commands:

```
gnuplot> g1(x) = x*tan(x)
gnuplot> g2(x) = sqrt(rho*rho - x*x)
gnuplot> plot [0:20][0:20] g1(x), g2(x)
```

The compilation and running of the program can be done as follows:

```
> gfortran nr.f90 -o nr
```
Figure 3.6: Plots of the right and left hand sides of equation (3.24). The intersections of the curves determine the solutions of the equation and their approximate graphical estimation can serve as initial points $x_0$ for the Newton-Raphson method.

</table>

We conclude that one of the roots of the equation is $\epsilon \approx 1.472473107$. The reader can compute more of these roots by following these steps by herself.

The method discussed above can be easily generalized to the case of two equations. Suppose that we need to solve simultaneously two algebraic equations $g_1(x_1, x_2) = 0$ and $g_2(x_1, x_2) = 0$. In order to compute a sequence $(x_{10}, x_{20}), (x_{11}, x_{21}), \ldots, (x_{1n}, x_{2n}), (x_{1(n+1)}, x_{2(n+1)}), \ldots$ that may converge to a root of the above system of equations, we Taylor expand...
3.4. THE NEWTON-RAPHSON METHOD

the two functions around \((x_1n, x_2n)\)

\[
g_1(x_{1(n+1)}, x_{2(n+1)}) = g_1(x_{1n}, x_{2n}) + (x_{1(n+1)} - x_{1n}) \frac{\partial g_1(x_{1n}, x_{2n})}{\partial x_1} + (x_{2(n+1)} - x_{2n}) \frac{\partial g_1(x_{1n}, x_{2n})}{\partial x_2} + \ldots
\]

\[
g_2(x_{1(n+1)}, x_{2(n+1)}) = g_2(x_{1n}, x_{2n}) + (x_{1(n+1)} - x_{1n}) \frac{\partial g_2(x_{1n}, x_{2n})}{\partial x_1} + (x_{2(n+1)} - x_{2n}) \frac{\partial g_2(x_{1n}, x_{2n})}{\partial x_2} + \ldots \quad (3.26)
\]

Defining \(\delta x_1 = (x_{1(n+1)} - x_{1n})\) and \(\delta x_2 = (x_{2(n+1)} - x_{2n})\) and setting \(g_1(x_{1(n+1)}, x_{2(n+1)}) \approx 0, g_2(x_{1(n+1)}, x_{2(n+1)}) \approx 0\), we obtain

\[
\begin{align*}
\delta x_1 \frac{\partial g_1}{\partial x_1} + \delta x_2 \frac{\partial g_1}{\partial x_2} &= -g_1 \\
\delta x_1 \frac{\partial g_2}{\partial x_1} + \delta x_2 \frac{\partial g_2}{\partial x_2} &= -g_2.
\end{align*} \quad (3.27)
\]

This is a linear \(2 \times 2\) system of equations

\[
\begin{align*}
A_{11} \delta x_1 + A_{12} \delta x_2 &= b_1 \\
A_{21} \delta x_1 + A_{22} \delta x_2 &= b_2,
\end{align*} \quad (3.28)
\]

where \(A_{ij} = \frac{\partial g_i}{\partial x_j}\) and \(b_i = -g_i\), with \(i, j = 1, 2\). Solving for \(\delta x_i\) we obtain

\[
\begin{align*}
x_{1(n+1)} &= x_{1n} + \delta x_1 \\
x_{2(n+1)} &= x_{2n} + \delta x_2.
\end{align*} \quad (3.29)
\]

The iterations stop when \(\delta x_i\) become small enough.

As an example, consider the equations with \(g_1(x) = 2x^2 - 3xy + y - 2\), \(g_2(x) = 3x + xy + y - 1\). We have \(A_{11} = 4x - 3y, A_{12} = 1 - 3x, A_{21} = 3 + y, A_{22} = 1 + x\). The program can be found in the file nr2.f90:

end subroutine solve2x2

In order to guess the region where the real roots of the systems lie, we make a 3-dimensional plot using gnuplot:

gnuplot> set isosamples 20
gnuplot> set hidden3d
gnuplot> splot 2*x**2-3*x*y+y-2.3*x+y*x+y-1.0

We plot the functions g_i(x, y) together with the plane x = 0. The intersection of the three surfaces determine the roots we are looking for. Compiling and running the program can be done by using the commands:
3.5. CALCULATION OF THE BIFURCATION POINTS

In order to determine the bifurcation points for \( r < r_c \) we will solve the algebraic equations \( x = f^{(k)}(x) \) and \( f^{(k)\prime}(x) = -1 \). At these points, \( k \)-cycles become unstable and \( 2k \)-cycles appear and are stable. This happens when \( r = r^{(n)} \), where \( k = 2^{n-2} \). We will look for solutions \((x^*_\alpha, r^{(n)}_c)\) for \( \alpha = k+1, k+2, \ldots, 2k \).

We define the functions \( F(x, r) = f(x) = rx(1-x) \) and \( F^{(k)}(x, r) = f^{(k)}(x) \) as in equation (3.6). We will solve the algebraic equations:

\[
\begin{align*}
g_1(x, r) &= x - F^{(k)}(x, r) = 0 \\
g_2(x, r) &= \frac{\partial F^{(k)}(x, r)}{\partial x} + 1 = 0.
\end{align*}
\]  

(3.30)

According to the discussion of the previous section, in order to calculate the roots of these equations we have to solve the linear system (3.28).
where the coefficients are
\[
\begin{align*}
  b_1 &= -g_1(x,r) = -x + F^{(k)}(x,r) \\
  b_2 &= -g_2(x,r) = -\frac{\partial F^{(k)}(x,r)}{\partial x} - 1 \\
  A_{11} &= \frac{\partial g_1(x,r)}{\partial x} = 1 - \frac{\partial F^{(k)}(x,r)}{\partial x} \\
  A_{12} &= \frac{\partial g_1(x,r)}{\partial r} = -\frac{\partial F^{(k)}(x,r)}{\partial r} \\
  A_{21} &= \frac{\partial g_2(x,r)}{\partial x} = \frac{\partial^2 F^{(k)}(x,r)}{\partial x^2} \\
  A_{22} &= \frac{\partial g_2(x,r)}{\partial r} = \frac{\partial^2 F^{(k)}(x,r)}{\partial x \partial r}.
\end{align*}
\]

(3.31)

The derivatives will be calculated approximately using finite differences
\[
\begin{align*}
  \frac{\partial F^{(k)}(x,r)}{\partial x} &\approx \frac{F^{(k)}(x+\epsilon, r) - F^{(k)}(x-\epsilon, r)}{2\epsilon} \\
  \frac{\partial F^{(k)}(x,r)}{\partial r} &\approx \frac{F^{(k)}(x, r+\epsilon) - F^{(k)}(x, r-\epsilon)}{2\epsilon},
\end{align*}
\]

(3.32)

and similarly for the second derivatives
\[
\begin{align*}
  \frac{\partial^2 F^{(k)}(x,r)}{\partial x^2} &\approx \frac{\frac{\partial F^{(k)}(x+\frac{\epsilon}{2}, r)}{\partial x} - \frac{\partial F^{(k)}(x-\frac{\epsilon}{2}, r)}{\partial x}}{2\epsilon^2} \\
  &\approx \frac{1}{\epsilon} \left\{ \frac{F^{(k)}(x+\epsilon, r) - F^{(k)}(x, r)}{\epsilon} - \frac{F^{(k)}(x, r) - F^{(k)}(x-\epsilon, r)}{\epsilon} \right\} \\
  &\approx \frac{1}{\epsilon^2} \left\{ F^{(k)}(x+\epsilon, r) - 2F^{(k)}(x, r) + F^{(k)}(x-\epsilon, r) \right\} \\
  \frac{\partial^2 F^{(k)}(x,r)}{\partial x \partial r} &\approx \frac{\frac{\partial F^{(k)}(x, r+\epsilon x)}{\partial r} - \frac{\partial F^{(k)}(x, r-\epsilon x)}{\partial r}}{2\epsilon \epsilon_x} \\
  &\approx \frac{1}{2\epsilon_x} \left\{ \frac{F^{(k)}(x+\epsilon_x, r+\epsilon_r) - F^{(k)}(x+\epsilon_x, r-\epsilon_r)}{\epsilon_r} - \frac{F^{(k)}(x-\epsilon_x, r+\epsilon_r) - F^{(k)}(x-\epsilon_x, r-\epsilon_r)}{\epsilon_r} \right\} \\
  &\approx \frac{1}{4\epsilon_x \epsilon_r} \left\{ F^{(k)}(x+\epsilon_x, r+\epsilon_r) - F^{(k)}(x+\epsilon_x, r-\epsilon_r) - F^{(k)}(x-\epsilon_x, r+\epsilon_r) + F^{(k)}(x-\epsilon_x, r-\epsilon_r) \right\}.
\end{align*}
\]

(3.33)

We are now ready to write the program for the Newton-Raphson method like in the previous section. The only difference is the approximate calculation of the derivatives using the relations above and the calculation
3.5. **CALCULATION OF THE BIFURCATION POINTS**

of the function \( F^{(k)}(x,r) \) by a routine that will compose the function \( f(x) \) \( k \)-times. The program can be found in the file `bifurcationPoints.f90`:

Function \( F(k,x,r) \) and its derivatives
```

---

**Note:** The provided code snippet is a Fortran program designed to calculate bifurcation points of the discrete logistic map at period \( k \) by solving the conditions \( g1(x,r) = x - F(k,x,r) = 0 \) and \( g2(x,r) = dF(k,x,r)/dx + 1 = 0 \). The equations are implemented using the Newton–Raphson method. The program inputs the period \( k \), initial values \( r_0 \) and \( x_0 \), and iterates \( F(x,r) = r*x*(x-1) \) \( k \) times to find bifurcation points. The Jacobian matrix is calculated to solve a 2x2 linear system, and the iteration continues until the error is less than a specified tolerance. The final output includes the iteration count, updated \( x_0 \), \( r_0 \), and error until convergence is achieved.

### 3.5. Calculation of the Bifurcation Points

\[ \text{epsx} = 1.0D-6x \]
\[ \text{epsr} = 1.0D-6r \]
\[ d2Fdrdx = \frac{F(k,x+\text{epsx}.r+\text{epsr})-F(k,x+\text{epsx}.r-\text{epsr}) \& \}
\[ -F(k,x-\text{epsx}.r+\text{epsr})+F(k,x-\text{epsx}.r-\text{epsr})}{(4.0D0*\text{epsx}*\text{epsr})} \]

```fortran
end function d2Fdrdx
```

Subroutine `solve2x2(A,b,dx)`

```fortran
implicit none
real(8) :: A(2,2), b(2), dx(2)
real(8) :: num1, num2, det
num1 = A(2,2)*b(1) - A(1,2)*b(2)
num2 = A(1,1)*b(2) - A(2,1)*b(1)
det = A(1,1)*A(2,2) - A(1,2)*A(2,1)
if(det .eq. 0.0D0) stop 'solve2x2: det = 0'
dx(1) = num1/det
dx(2) = num2/det
end subroutine solve2x2
```

Compiling and running the program can be done as follows:

```
> gfortran bifurcationPoints.f90 -o b
> echo 2 3.5 0.5 | ./b
```

The above listing shows the points of the 2-cycle and some of the points of the 4-cycle. It is also possible to compare the calculated value \( r_c^{(3)} = 3.449490132 \) with the expected one \( r_c^{(3)} = 1 + \sqrt{6} \approx 3.449489742 \). Improving the accuracy of the calculation is left as an exercise for the reader who has to control the systematic errors of the calculations and achieve better accuracy in the computation of \( r_c^{(3)} \).
3.6 Liapunov Exponents

We have seen that when \( r > r_c \approx 3.56994567 \), the trajectories of the logistic map become non periodic and exhibit chaotic behavior. Chaotic behavior mostly means sensitivity of the evolution of a dynamical system to the choice of initial conditions. More precisely, it means that two different trajectories constructed from infinitesimally close initial conditions, diverge very fast from each other. This implies that there is a set of initial conditions that densely cover subintervals of \((0, 1)\) whose trajectories do not approach arbitrarily close to any cycle of finite length.

Assume that two trajectories have \( x_0, \tilde{x}_0 \) as initial points and \( \Delta x_0 = x_0 - \tilde{x}_0 \). When the points \( x_n, \tilde{x}_n \) have a distance \( \Delta x_n = \tilde{x}_n - x_n \) that for small enough \( n \) increases exponentially with \( n \) (the “time”), i.e.

\[
\Delta x_n \sim \Delta x_0 e^{\lambda n}, \quad \lambda > 0,
\]

the system is most likely exhibiting chaotic behavior\[\text{[Ts]}.\] The exponent \( \lambda \) is called a Liapunov exponent. A useful equation for the calculation of \( \lambda \) is

\[
\lambda = \lim_{n \to \infty} \frac{1}{n} \sum_{k=0}^{n-1} \ln |f'(x_k)|.
\]

This relation can be easily proved by considering infinitesimal \( \epsilon \equiv |\Delta x_0| \)

\[\text{[Ts]}\] Sensitivity to the initial condition alone does not necessarily imply chaos. It is necessary to have topological mixing and dense periodic orbits. Topological mixing means that every open set in phase space will evolve to a set that for large enough time will have non zero intersection with any open set. Dense periodic orbits means that every point in phase space lies infinitesimally close to a periodic orbit.
so that $\lambda = \lim_{n \to \infty} \lim_{\epsilon \to 0} \frac{1}{n} \ln |\Delta x_n|/\epsilon$. Then we obtain

$$\dot{x}_1 = f(x_0) = f(x_0 + \epsilon) \approx f(x_0) + \epsilon f'(x_0)$$

$$\frac{\Delta x_1}{\epsilon} = \frac{\dot{x}_1 - x_1}{\epsilon} \approx f'(x_0)$$

$$\dot{x}_2 = f(x_1) = f(x_1 + \epsilon f'(x_0)) \approx f(x_1) + (\epsilon f'(x_0)) f'(x_1)$$

$$\frac{\Delta x_2}{\epsilon} = \frac{\dot{x}_2 - x_2}{\epsilon} \approx f'(x_0) f'(x_1)$$

$$\dot{x}_3 = f(x_2) = f(x_2 + \epsilon f'(x_0) f'(x_1)) \approx f(x_2) + (\epsilon f'(x_0) f'(x_1)) f'(x_2)$$

$$\frac{\Delta x_3}{\epsilon} = \frac{\dot{x}_3 - x_3}{\epsilon} \approx f'(x_0) f'(x_1) f'(x_2). \quad (3.36)$$

We can show by induction that $|\Delta x_n|/\epsilon \approx f'(x_0) f'(x_1) f'(x_2) \ldots f'(x_{n-1})$ and by taking the logarithm and the limits we can prove (3.35).

A first attempt to calculate the Liapunov exponents could be made by using the definition (3.34). We modify the program logistic.f90 so that it calculates two trajectories whose initial distance is $\epsilon = \text{epsilon}$:

```fortran
! Discrete Logistic Map:
! Two trajectories with close initial conditions.
!
program logistic_map
  implicit none
  integer :: NSTEPS, i
  real(8) :: r, x0, x1, x0t, x1t, epsilon

! ----- Input:
  print *, '# Enter NSTEPS, r, x0, epsilon:'
  read *, NSTEPS, r, x0, epsilon
  print *, '# NSTEPS = ', NSTEPS
  print *, '# r = ', r
  print *, '# x0 = ', x0
  print *, '# epsilon = ', epsilon

  x0t = x0 + epsilon

! ----- Initialize:
  open(unit=33, file='lia.dat')
  write(33,*) 1, x0, x0t, ABS(x0t-x0)/epsilon
```

Figure 3.7: A plot of $|\Delta x_n|/\epsilon$ for the logistic map for $r = 3.6$, $x_0 = 0.2$. Note the convergence of the curves as $\epsilon \to 0$ and the approximate exponential behavior in this limit. The two lines are fits to the equation (3.34) and give $\lambda = 0.213(4)$ and $\lambda = 0.217(6)$ respectively.

After running the program, the quantity $|\Delta x_n|/\epsilon$ is found at the fourth column of the file lia.dat. The curves of figure 3.7 can be constructed by using the commands:

```bash
> gfortran liapunov1.f90 -o l
> gnuplot
> gnuplot> set logscale y
> gnuplot> plot \
> "<echo 200 3.6 0.2 1e-15 1./1;cat lia.dat" u 1:4 w l
```
The last line plots the stdout of the command "echo 200 3.6 0.2 1e-15 \\./l;cat lia.dat", i.e. the contents of the file lia.dat produced after running our program using the parameters NSTEPS = 200, r = 3.6, x0 = 0.2 and epsilon = 10 \textsuperscript{-15}. The gnuplot command set logscale y, puts the y axis in a logarithmic scale. Therefore an exponential function is shown as a straight line and this is what we see in figure 3.7: The points $|\Delta x_n|/\epsilon$ tend to lie on a straight line as $\epsilon$ decreases. The slopes of these lines are equal to the Liapunov exponent $\lambda$. Deviations from the straight line behavior indicates corrections and systematic errors, as we point out in figure 3.7. A different initial condition results in a slightly different value of $\lambda$, and the true value can be estimated as the average over several such choices. We estimate the error of our computation from the standard error of the mean. The reader should perform such a computation as an exercise.

One can perform a fit of the points $|\Delta x_n|/\epsilon$ to the exponential function in the following way: Since $|\Delta x_n|/\epsilon \sim C \exp(\lambda n) \Rightarrow \ln(|\Delta x_n|/\epsilon) = \lambda n + c$, we can make a fit to a straight line instead. Using gnuplot, the relevant commands are:

```
                    gnuplot> fit [5:53] a*x+b  \n                        "<echo 500 3.6 0.2 1e-15 1./1;cat lia.dat"\n                    using 1:(log($4)) via a,b
                    gnuplot> replot exp(a*x+b)
```

The command shown above fits the data to the function $a*x+b$ by taking the 1st column and the logarithm of the 4th column (using 1:(log($4$))) of the stdout of the command that we used for creating the previous plot. We choose data for which 5 \leq n \leq 53 ([5:53]) and the fitting parameters are a,b (via a,b). The second line, adds the fitted function to the plot.

Now we are going to use equation (3.35) for calculating $\lambda$. This equation is approximately correct when (a) we have already reached the steady state and (b) in the large $n$ limit. For this reason we should study if we obtain a satisfactory convergence when we (a) “throw away” a number of NTRANS steps, (b) calculate the sum (3.35) for increasing NSTEPS= n (c) calculate the sum (3.35) for many values of the initial point $x_0$. This has to be carefully repeated for all values of $r$ since each factor will contribute differently to the quality of the convergence: In regions that manifest chaotic behavior (large $\lambda$) convergence will be slower. The program can be found in the file liapunov2.f90:
Figure 3.8: Plot of the sum \((1/n) \sum_{k=N}^{N+n-1} \ln |f'(x_k)|\) as a function of \(n\) for the logistic map with \(r = 3.8\), \(N = 2000\) for different initial conditions \(x_0 = 0.20, 0.35, 0.50, 0.75, 0.90\). The different curves converge in the limit \(n \to \infty\) to \(\lambda = 0.4325(10)\).

```
program logistic_map
  implicit none
  integer :: NTRANS, NSTEPS, i
  real(8) :: r, x0, x1, sum

  ! Input:
  print *, '# Enter NTRANS, NSTEPS, r, x0:'
  read *, NTRANS, NSTEPS, r, x0
  print *, '# NTRANS = ', NTRANS
  print *, '# NSTEPS = ', NSTEPS
  print *, '# r = ', r
  print *, '# x0 = ', x0

  do i=1,NTRANS
    x1 = r * x0 * (1.0D0-x0 )
  end do
```
3.6. LIAPUNOV EXPONENTS

enddo
sum = log(ABS(r*(1.0D0-2.0D0*x0)))
! Initialize:
open(unit=33,file='lia.dat')
write(33,*) 1,x0,sum
! Calculate:
do i=2,NSTEPS
  x1 = r * x0 * (1.0D0-x0)
  sum = sum + log(ABS(r*(1.0D0-2.0D0*x1)))
  write(33,*) i,x1,sum/i
x0 = x1
endo
close(33)
end program logistic_map

After NTRANS steps, the program calculates NSTEPS times the sum of the terms \( \ln |f'(x_k)| = \ln |r(1-2x_k)|. \) At each step the sum divided by the number of steps \( i \) is printed to the file lia.dat. Figure 3.6 shows the results for \( r = 3.8 \). This is a point where the system exhibits strong chaotic behavior and convergence is achieved after we compute a large number of steps. Using NTRANS = 2000 and NSTEPS \approx 70000 \) the achieved accuracy is about 0.2\% with \( \lambda = 0.4325 \pm 0.0010 = 0.4325(10) \). The main contribution to the error comes from the different paths followed by each initial point chosen. The plot can be constructed with the gnuplot commands:

\[
> \text{gfortran liapunov2.f90 \\
> gnuplot \\
> gnuplot> plot \\
> "<echo 2000 70000 3.8 0.20 l./l;cat lia.dat” u 1:3 w l,\}
> "<echo 2000 70000 3.8 0.35 l./l;cat lia.dat” u 1:3 w l,\}
> "<echo 2000 70000 3.8 0.50 l./l;cat lia.dat” u 1:3 w l,\}
> "<echo 2000 70000 3.8 0.75 l./l;cat lia.dat” u 1:3 w l,\}
> "<echo 2000 70000 3.8 0.90 l./l;cat lia.dat” u 1:3 w l
\]

The plot command runs the program using the parameters NTRANS = 2000, NSTEPS = 70000, \( r = 3.8 \) and \( x0 = 0.20,0.35,0.50,0.75,0.90 \) and plots the results from the contents of the file lia.dat.

In order to determine the regions of chaotic behavior we have to study the dependence of the Liapunov exponent \( \lambda \) on the value of \( r \). Using our experience coming from the careful computation of \( \lambda \) before, we will run the program for several values of \( r \) using the parameters NTRANS = 2000, NSTEPS = 60000 from the initial point \( x0 = 0.2 \). This calculation gives accuracy of the order of 1\%. If we wish to measure \( \lambda \) carefully and estimate the error of the results, we have to follow the steps described in
The program can be found in the file liapunov3.f90 and it is a simple modification of the previous program so that it can perform the calculation for many values of \( r \).

The program can be compiled and run using the commands:
The character & makes the program ./l to run in the background. This is recommended for programs that run for a long time, so that the shell returns the prompt to the user and the program continues to run even after the shell is terminated.

![Liapunov exponent graph]

**Figure 3.9:** The Liapunov exponent $\lambda$ of the logistic map calculated via equation (3.35). Note the chaotic behavior that manifests for the values of $r$ where $\lambda > 0$ and the windows of stable $k$-cycles where $\lambda < 0$. Compare this plot with the bifurcation diagram of figure 3.4. At the points where $\lambda = 0$ we have onset of chaos (or “edge of chaos”) with manifestation of weak chaos (i.e. $|\Delta x_n| \sim |\Delta x_0| n^\omega$). At these points we have transitions from stable $k$-cycles to strong chaos. We observe the onset of chaos for the first time when $r = r_c \approx 3.5699$, at which point $\lambda = 0$ (for smaller $r$ the plot seems to touch the $\lambda = 0$ line, but in fact $\lambda$ takes negative values with $|\lambda|$ very small).

The data are saved in the file lia.dat and we can make the plot shown in figure [3.7] using gnuplot:

```
gnuplot> plot "lia.dat" with lines notitle .0 notitle
```

Now we can compare figure [3.9] with the bifurcation diagram shown in figure [3.4]. The intervals with $\lambda < 0$ correspond to stable $k$-cycles. The
intervals where $\lambda > 0$ correspond to manifestation of *strong chaos*. These intervals are separated by points with $\lambda = 0$ where the system exhibits *weak chaos*. This means that neighboring trajectories diverge from each other with a power law $|\Delta x_n| \sim |\Delta x_0|n^\omega$ instead of an exponential, where $\omega = 1/(1 - q)$ is a positive exponent that needs to be determined. The parameter $q$ is the one usually used in the literature. Strong chaos is obtained in the $q \to 1$ limit. For larger $r$, switching between chaotic and stable periodic trajectories is observed each time $\lambda$ changes sign. The critical values of $r$ can be computed with relatively high accuracy by restricting the calculation to a small enough neighborhood of the critical point. You can do this using the program listed above by setting the parameters $r_{\text{min}}$ and $r_{\text{max}}$.

![Figure 3.10](image)

**Figure 3.10:** The distribution functions $p(x)$ of $x$ of the logistic map for $r = 3.59$ (left) and 3.8 (right). The chaotic behavior appears to be weaker for $r = 3.59$, and this is reflected on the value of the entropy. One sees that there exist intervals of $x$ with $p(x) = 0$ which become smaller and vanish as $r$ gets close to 4. This distribution is very hard to be distinguished from a truly random distribution.

We can also study the chaotic properties of the trajectories of the logistic map by computing the distribution $p(x)$ of the values of $x$ in the interval $(0, 1)$. After the transitional period, the distribution $p(x)$ for the $k$ cycles will have support only at the points of the $k$ cycles, whereas for the chaotic regimes it will have support on subintervals of $(0, 1)$. The distribution function $p(x)$ is independent for most of the initial points of the trajectories. If one obtains a large number of points from many trajectories of the logistic map, it will be practically impossible to understand that these are produced by a deterministic rule. For this reason, chaotic systems can be used for the production of *pseudorandom* numbers, as we will see in chapter 11. By measuring the *entropy*, which is a measure of disorder in a system, we can quantify the “randomness” of
the distribution. As we will see in chapter 12, it is given by the equation

\[ S = - \sum_k p_k \ln p_k, \]  

(3.37)

where \( p_k \) is the probability of observing the state \( k \). In our case, we can make an approximate calculation of \( S \) by dividing the interval \((0,1)\) into \( N \) subintervals of width \( \Delta x \). For given \( r \) we obtain a large number \( M \) of values \( x_n \) of the logistic map and we compute the histogram \( h_k \) of their distribution in the intervals \((x_k, x_k + \Delta x)\). The probability density is obtained from the limit of \( p_k = h_k / (M \Delta x) \) as \( M \) becomes large and \( \Delta x \) small (large \( N \)). Indeed, \( \sum_{k=1}^N p_k \Delta x = 1 \) converges to \( \int_0^1 p(x) \, dx = 1 \). We will define \( S = -\sum_{k=1}^N p_k \ln p_k \Delta x \).

\[ \begin{align*}
\text{Figure 3.11: The distribution } p(x) \text{ of } x \text{ for the logistic map for } r = 4. \text{ We observe strong chaotic behavior, } p(x) \text{ has support over the whole interval } (0,1) \text{ and the entropy is large. The solid line is the analytic form of the distribution } p(x) = \pi^{-1} x^{-1/2} (1-x)^{-1/2} \text{ which is known for } r = 4 \text{ [30]. This is the beta distribution for } a = 1/2, b = 1/2.
\end{align*} \] 

The program listed below calculates \( p_k \) for chosen values of \( r \), and then the entropy \( S \) is calculated using (3.37). It is a simple modification of the program in liapunov3.f90 where we add the parameter NHIST counting the number of intervals \( N \) for the histograms. The probability density is calculated in the array p(NHIST). The program can be found in the file entropy.f90:
Discrete Logistic Map:

Entropy calculation from \( S = \sum_i p_i \ln p_i \)

Calculation for \( r \) in \([r_{min}, r_{max}]\) with \( RSTEPS \) steps

\( NHIST \): number of histogram bins for calculation of \( p_i \)

\( NSTEPS \): number of values of \( x \) in the histograms

\( NTRANS \): number of discarded iterations in order to discard transient behavior

\( x_{start} \): value of initial \( x_0 \) for every \( r \)

---

```fortran
program logistic_map
  implicit none
  real(8), parameter :: rmin = 2.5D0
  real(8), parameter :: rmax = 4.0D0
  real(8), parameter :: xstart = 0.2D0
  integer, parameter :: RSTEPS = 1000
  integer, parameter :: NHIST = 10000
  integer, parameter :: NTRANS = 2000
  integer, parameter :: NSTEPS = 5000000
  real(8), parameter :: xmin=0.0D0, xmax=1.0D0
  integer :: i, ir, isum, n
  real(8) :: r, x0, x1, sum, dr, dx
  real(8) :: p(NHIST), S

  open(unit=33, file='entropy.dat')
  p = 0.0D0
  dr = (rmax-rmin)/(RSTEPS-1)
  dx = (xmax-xmin)/(NHIST-1)
  do ir=0,RSTEPS-1
    r = rmin+ir*dr
    x0 = xstart
    do i=1,NTRANS
      x1 = r * x0 * (1.0D0-x0)
      x0 = x1
    enddo
    !make histogram:
    n=INT(x0/dx)+1: p(n)=p(n)+1.0D0
  do i=2,NSTEPS
    x1 = r * x0 * (1.0D0-x0)
    n = INT(x1/dx)+1
    p(n)=p(n)+1.0D0
    x0 = x1
  enddo
  !p(k) is now histogram of x-values.
  !Normalize so that \( \sum_k p(k)dx = 1 \)

**Figure 3.12:** The entropy \( S = -\sum p_k \ln p_k \Delta x \) for the logistic map as a function of \( r \). The vertical line is \( r_c \approx 3.56994567 \) which marks the beginning of chaos and the horizontal is the corresponding entropy. The entropy is low for small values of \( r \), where we have the stable \( 2^n \) cycles, and large in the chaotic regimes. \( S \) drops suddenly when we pass to a (temporary) periodic behavior interval. We clearly observe the 3-cycle for \( r = 1 + \sqrt{8} \approx 3.8384 \) and the subsequent bifurcations that we observed in the bifurcation diagram (figure 3.4) and the Liapunov exponent diagram (figure 3.9).

For the calculation of the distribution functions and the entropy we have to choose the parameters which control the systematic error. The parameter \( \text{NTRANS} \) should be large enough so that the transitional behavior will not contaminate our results. Our measurements must be checked...
for being independent of its value. The same should be done for the ini-
tial point $x_{\text{start}}$. The parameter $NHIST$ controls the partitioning of the
interval $(0, 1)$ and the width $\Delta x$, so it should be large enough. The pa-
rameter $NSTEPS$ is the number of “measurements” for each value of $r$ and
it should be large enough in order to reduce the “noise” in $p_k$. It is obvi-
ous that $NSTEPS$ should be larger when $\Delta x$ becomes smaller. Appropriate
choices lead to the plots shown in figures 3.10 and 3.11 for $r = 3.59, 3.58$
and 4. We see that stronger chaotic behavior means a wider distribution
of the values of $x$.

The entropy is shown in figure 3.12. The stable periodic trajectories
lead to small entropy, whereas the chaotic ones lead to large entropy.
There is a sudden increase in the value of the entropy at the beginning
of chaos at $r = r_c$, which increases even further as the chaotic behavior
becomes stronger. During the intermissions of the chaotic behavior there
are sudden drops in the value of the entropy. It is quite instructive to
compare the entropy diagrams with the corresponding bifurcation dia-
grams (see figure 3.4) and the Liapunov exponent diagrams (see figure
3.9). The entropy is increasing until $r$ reaches its maximum value 4, but
this is not done smoothly. By magnifying the corresponding areas in the
plot, we can see an infinite number of sudden drops in the entropy in
intervals of $r$ that become more and more narrow.
3.7 Problems

Several of the programs that you need to write for solving the problems of this chapter can be found in the Problems directory of the accompanying software of this chapter.

3.1 Confirm that the trajectories of the logistic map for $r < 1$ are falling off exponentially for large enough $n$.

(a) Choose $r = 0.5$ and plot the trajectories for $x_0 = 0.1 - 0.9$ with step 0.1 for $n = 1, \ldots, 1000$. Put the $y$ axis in a logarithmic scale. From the resulting curves discuss whether you obtain an exponential falloff.

(b) Fit the points $x_n$ for $n > 20$ to the function $ce^{-ax}$ and determine the fitting parameters $a$ and $c$. How do these parameters depend on the initial point $x_0$? You can use the following gnuplot commands for your calculation:

```
 gnuplot> !gfortran logistic.f90 -o l
 gnuplot> a=0.7;c=0.4;
 gnuplot> fit [10:] c*exp(-a*x) \n"<echo 1000 0.5 0.51/1;cat log.dat" via a,c
 gnuplot> plot c*exp(-a*x),\n"<echo 1000 0.5 0.51/1;cat log.dat" w l
```

As you can see, we set NSTEPS = 1000, $r = 0.5$, $x_0 = 0.5$. By setting the limits [10:] to the fit command, the fit includes only the points $x_n \geq 10$, therefore avoiding the transitional period and the deviation from the exponential falloff for small $n$.

(c) Repeat for $r = 0.3 - 0.9$ with step 0.1 and for $r = 0.99, 0.999$. As you will be approaching $r = 1$, you will need to discard more points from near the origin. You might also need to increase NSTEPS. You should always check graphically whether the fitted exponential function is a good fit to the points $x_n$ for large $n$. Construct a table for the values of $a$ as a function of $r$.

The solutions of the equation (3.3) is $e^{(r-1)x}$. How is this related to the values that you computed in your table?

3.2 Consider the logistic map for $r = 2$. Choose NSTEPS=100 and calculate the corresponding trajectories for $x_0 = 0.2, 0.3, 0.5, 0.7$, ...
0.9. Plot them on the same graph. Calculate the fixed point $x_2^*$ and compare your result to the known value $1 - 1/r$. Repeat for $x_0 = 10^{-a}$ for $a = -1, -2, -5, -10, -20, -25$. What do you conclude about the point $x_1^* = 0$?

3.3 Consider the logistic map for $r = 2.9, 2.99, 2.999$. Calculate the stable point $x_2^*$ and compare your result to the known value $1 - 1/r$. How large should $\text{NSTEPS}$ be chosen each time? You may choose $x_0 = 0.3$.

3.4 Consider the logistic map for $r = 3.2$. Take $x_0 = 0.3, 0.5, 0.9$ and $\text{NSTEPS}=300$ and plot the resulting trajectories. Calculate the fixed points $x_3^*$ and $x_4^*$ by using the command `tail log.dat`. Increase $\text{NSTEPS}$ and repeat so that you make sure that the trajectory has converged to the 2-cycle. Compare their values to the ones given by equation (3.18). Make the following plots:

```
set samples 1000
f(x) = r*x*(1-x)
r=1; plot [0:1] x, f(x), f(f(x)), f(f(f(x))), f(f(f(f(x)))))
```

What do you observe?

3.5 Repeat the previous problem for $r = 3.4494$. How big should $\text{NSTEPS}$ be chosen so that you obtain $x_3^*$ and $x_4^*$ with an accuracy of 6 significant digits?

3.6 Repeat the previous problem for $r = 3.5$ and 3.55. Choose $\text{NSTEPS} = 10000$, $x_0 = 0.5$. Show that the trajectories approach a 4-cycle and an 8-cycle respectively. Calculate the fixed points $x_5^*-x_8^*$ and $x_9^*-x_{16}^*$.

3.7 Plot the functions $f(x), f^{(2)}(x), f^{(4)}(x), x$ for given $r$ on the same graph. Use the commands:

```
set samples 1000
f(x) = r*x*(1-x)
r=1; plot [0:1] x, f(x), f(f(x)), f(f(f(x))), f(f(f(f(x)))))
```

The command `r=1` sets the value of $r$. Take $r = 2.5, 3, 3.2, 1+\sqrt{6}, 3.5$. Determine the fixed points and the $k$-cycles from the intersections of the plots with the diagonal $y = x$. 
3.8 Construct the cobweb plots of figures 3.2 and 3.4 for \( r = 2.8, 3.3 \) and 3.5. Repeat by dropping from the plot an increasing number of initial points, so that in the end only the \( k \)-cycles will remain. Do the same for \( r = 3.55 \).

3.9 Construct the bifurcation diagrams shown in figure 3.4.

3.10 Construct the bifurcation diagram of the logistic map for \( 3.840 < r < 3.851 \) and for \( 0.458 < x < 0.523 \). Compute the first four bifurcation points with an accuracy of 5 significant digits by magnifying the appropriate parts of the plots. Take \( N_{\text{TRANS}} = 15000 \).

3.11 Construct the bifurcation diagram of the logistic map for \( 2.9 < r < 3.57 \). Compute graphically the bifurcation points \( r_c^{(n)} \) for \( n = 2, 3, 4, 5, 6, 7, 8 \). Make sure that your results are stable against variations of the parameters \( N_{\text{TRANS}}, N_{\text{STEPS}} \) as well as from the choice of branching point. From the known values of \( r_c^{(n)} \) for \( n = 2, 3 \), and from the dependence of your results on the choices of \( N_{\text{TRANS}}, N_{\text{STEPS}}, \) estimate the accuracy achieved by this graphical method. Compute the ratios \( (r_c^{(n)} - r_c^{(n-1)})/(r_c^{(n+1)} - r_c^{(n)}) \) and compare your results to equation (3.20).

3.12 Choose the values of \( \rho \) in equation (3.24) so that you obtain only one energy level. Compute the resulting value of the energy. When do we have three energy levels?

3.13 Consider the polynomial \( g(x) = x^3 - 2x^2 - 11x + 12 \). Find the roots obtained by the Newton-Raphson method when you choose \( x_0 = 2.35287527, 2.35284172, 2.35283735, 2.352836327, 2.352836323 \). What do you conclude concerning the basins of attraction of each root of the polynomial? Make a plot of the polynomial in a neighborhood of its roots and try other initial points that will converge to each one of the roots.

3.14 Use the Newton-Raphson method in order to compute the 4-cycle \( x_5^*, \ldots, x_8^* \) of the logistic map. Use appropriate areas of the bifurcation diagram so that you can choose the initial points correctly. Check that your result for \( r_c^{(4)} \) is the same for all \( x_5^* \). Tune the parameters chosen in your calculation in order to improve the accuracy of your measurements.

3.15 Repeat the previous problem for the 8-cycle \( x_9^*, \ldots, x_{16}^* \) and \( r_c^{(5)} \).
Table 3.1: The values of $r_c^{(n)}$ for the logistic map calculated for problem 17. $r_c^{(\infty)} \equiv r_c$ is taken from the bibliography.

$r_c = 3.56994567\ldots$

3.16 Repeat the previous problem for the 16-cycle $x_{17}^*\ldots,x_{32}^*$ and $r_c^{(6)}$.

3.17 Calculate the critical points $r_c^{(n)}$ for $n = 3,\ldots,17$ of the logistic map using the Newton-Raphson method. In order to achieve that, you should determine the bifurcation points graphically in the bifurcation diagram first and then choose the initial points in the Newton-Raphson method appropriately. The program in bifurcationPoints.f90 should read the parameters eps, epsx, epsr from the stdin so that they can be tuned for increasing $n$. If these parameters are too small the convergence will be unstable and if they are too large you will have large systematic errors. Using this method, try to reproduce table 3.1.

3.18 Calculate the ratios $\Delta r_c^{(n)}/\Delta r_c^{(n+1)}$ of equation (3.20) using the results of table 3.1. Calculate Feigenbaum’s constant and comment on the accuracy achieved by your calculation.

3.19 Estimate Feigenbaum’s constant $\delta$ and the critical value $r_c$ by assuming that for large enough $n$, $r_c^{(n)} \approx r_c - C\delta^{-n}$. This behavior is a result of equation (3.20). Fit the results of table 3.1 to this function and calculate $\delta$ and $r_c$. This hypothesis is confirmed in figure 3.13 where we can observe the exponential convergence of $r_c^{(n)}$ to $r_c$. Construct the same plot using the parameters of your calculation.

Hint: You can use the following gnuplot commands:
3.7. PROBLEMS

The file \textit{rcrit} contains the values of table 3.1. You should vary the parameters \texttt{nmin}, \texttt{nmax} and repeat until you obtain a stable fit.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{relation图为input}
\caption{Test of the relation \(r_c^{(n)} \approx r_c - C \delta^{-n}\) discussed in problem 17. The parameters used in the plot are approximately \(r_c = 3.569457\), \(\delta = 4.669196\) and \(C = 12.292\).}
\end{figure}

3.20 Use the Newton-Raphson method to calculate the first three bifurcation points after the appearance of the 3-cycle for \(r = 1 + \sqrt{8}\). Choose one bifurcation point of the 3-cycle, one of the 6-cycle and one of the 12-cycle and magnify the bifurcation diagram in their neighborhood.

3.21 Consider the map describing the evolution of a population

\[ x_{n+1} = p(x_n) = x_n e^{r(1-x_n)}. \]  

(a) Plot the functions \(x, p(x), p^{(2)}(x), p^{(4)}(x)\) for \(r = 1.8, 2, 2.6, 2.67, 2.689\) for \(0 < x < 8\). For which values of \(r\) do you expect to obtain stable \(k\)-cycles?
b) For the same values of \( r \) plot the trajectories with initial points \( x_0 = 0.2, 0.5, 0.7 \). For each \( r \) make a separate plot.

c) Use the Newton-Raphson method in order to determine the points \( r_c^{(n)} \) for \( n = 3, 4, 5 \) as well as the first two bifurcation points of the 3-cycle.

d) Construct the bifurcation diagram for \( 1.8 < r < 4 \). Determine the point marking the onset of chaos as well as the point where the 3-cycle starts. Magnify the diagram around a branch that you will choose.

e) Estimate Feigenbaum’s constant \( \delta \) as in problem 17. Is your result compatible with the expectation of universality for the value of \( \delta \)? Is the value of \( r_c \) the same as that of the logistic map?

3.22 Consider the sine map:

\[
x_{n+1} = s(x_n) = r \sin(\pi x_n).
\]  

(a) Plot the functions \( x, s(x), s^{(2)}(x), s^{(4)}(x), s^{(8)}(x) \) for \( r = 0.65, 0.75, 0.84, 0.86, 0.88 \). Which values of \( r \) are expected to lead to stable \( k \)-cycles?

(b) For the same values of \( r \), plot the trajectories with initial points \( x_0 = 0.2, 0.5, 0.7 \). Make one plot for each \( r \).

c) Use the Newton-Raphson method in order to determine the points \( r_c^{(n)} \) for \( n = 3, 4, 5 \) as well as the first two bifurcation points of the 3-cycle.

d) Construct the bifurcation diagram for \( 0.6 < r < 1 \). Within which limits do the values of \( x \) lie in? Repeat for \( 0.6 < r < 2 \). What do you observe? Determine the point marking the onset of chaos as well as the point where the 3-cycle starts. Magnify the diagram around a branch that you will choose.

3.23 Consider the map:

\[
x_{n+1} = 1 - r x_n^2.
\]  

(a) Construct the bifurcation diagram for \( 0 < r < 2 \). Within which limits do the values of \( x \) lie in? Determine the point marking the onset of chaos as well as the point where the 3-cycle starts. Magnify the diagram around a branch that you will choose.
3.7. PROBLEMS

(b) Use the Newton-Raphson method in order to determine the points \( r_c^{(n)} \) for \( n = 3, 4, 5 \) as well as the first two bifurcation points of the 3-cycle.

3.24 Consider the tent map:

\[
x_{n+1} = r \min\{x_n, 1 - x_n\} = \begin{cases} 
rx_n & 0 \leq x_n \leq \frac{1}{2} \\
(1 - x_n) & \frac{1}{2} < x_n \leq 1 
\end{cases}.
\] (3.41)

Construct the bifurcation diagram for \( 0 < r < 2 \). Within which limits do the values of \( x \) lie in? On the same graph, plot the functions \( r/2, r - r^2/2 \).

Magnify the diagram in the area \( 1.407 < r < 1.416 \) and \( 0.580 < x < 0.588 \). At which point do the two disconnected intervals within which \( x_n \) take their values merge into one? Magnify the areas \( 1.0 < r < 1.1, 0.4998 < x < 0.5004 \) and \( 1.00 < r < 1.03, 0.4999998 < x < 0.5000003 \) and determine the merging points of two disconnected intervals within which \( x_n \) take their values.

3.25 Consider the Gauss map (or mouse map):

\[
x_{n+1} = e^{-rx_n^2} + q .
\] (3.42)

Construct the bifurcation diagram for \( -1 < q < 1 \) and \( r = 4.5, 4.9, 7.5 \). Make your program to take as the initial point of the new trajectory to be the last one of the previous trajectory and choose \( x_0 = 0 \) for \( q = -1 \). Repeat for \( x_0 = 0.7, 0.5, -0.7 \). What do you observe? Note that as \( q \) is increased, we obtain bifurcations and “anti-bifurcations”.

3.26 Consider the circle map:

\[
x_{n+1} = [x_n + r \sin(2\pi x_n)] \mod 1 .
\] (3.43)

(Make sure that your program keeps the values of \( x_n \) so that \( 0 \leq x_n < 1 \). Construct the bifurcation diagram for \( 0 < q < 2 \) and \( r = 1/3 \).

3.27 Use the program in liapunov.f90 in order to compute the distance between two trajectories of the logistic map for \( r = 3.6 \) that originally are at a distance \( \Delta x_0 = 10^{-15} \). Choose \( x_0 = 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 0.99, 0.999 \) and calculate the Liapunov exponent by fitting to a straight line appropriately. Compute the mean value and the standard error of the mean.
3.28 Calculate the Liapunov exponent for \( r = 3.58, 3.60, 3.65, 3.70, 3.80 \) for the logistic map. Use both ways mentioned in the text. Choose at least 5 different initial points and calculate the mean and the standard error of the mean of your results. Compare the values of \( \lambda \) that you obtain with each method and comment.

3.29 Compute the critical value \( r_c \) numerically as the limit \( \lim_{n \to \infty} r^{(n)}_c \) for the logistic map with an accuracy of nine significant digits. Use the calculation of the Liapunov exponent \( \lambda \) given by equation (3.35).

3.30 Compute the values of \( r \) of the logistic map numerically for which we (a) enter a stable 3-cycle (b) reenter into the chaotic behavior. Do the calculation by computing the Liapunov exponent \( \lambda \) and compare your results with the ones obtained from the bifurcation diagram.

3.31 Calculate the Liapunov exponent using equation (3.35) for the following maps:

\[
\begin{align*}
x_{n+1} &= x_n e^{r(1-x_n)}, & 1.8 < r < 4 \\
x_{n+1} &= r \sin(\pi x_n), & 0.6 < r < 1 \\
x_{n+1} &= 1 - r x_n^2, & 0 < r < 2 \\
x_{n+1} &= e^{-r x_n^2} + q, & r = 7.5, -1 < q < 1 \\
x_{n+1} &= \left[x_n + \frac{1}{3} - q \sin(2\pi x_n)\right] \mod 1, & 0 < q < 2
\end{align*}
\]

and construct the diagrams similar to the ones in figure 3.9. Compare your plots with the respective bifurcation diagrams (you may put both graphs on the same plot). Use two different initial points \( x_0 = 0, 0.2 \) for the Gauss map \( x_{n+1} = e^{-r x_n^2} + q \) and observe the differences. For the circle map \( x_{n+1} = [x_n + 1/3 - q \sin(2\pi x_n)] \mod 1 \) study carefully the values \( 0 < q < 0.15 \).

3.32 Reproduce the plots in figures 3.10, 3.11 and 3.12. Compute the function \( p(x) \) for \( r = 3.68, 3.80, 3.93 \) and 3.98. Determine the points where you have stronger chaos by observing \( p(x) \) and the corresponding values of the entropy. Compute the entropy for \( r \in (3.95, 4.00) \) by taking \( \text{RSTEPS}=2000 \) and estimate the values of \( r \) where we enter to and exit from chaos. Compare your results with the computation of the Liapunov exponent.
3.7. PROBLEMS

3.33 Consider the Hénon map:

\[
\begin{align*}
x_{n+1} &= y_n + 1 - ax_n^2 \\
y_{n+1} &= bx_n
\end{align*}
\]  

(a) Construct the two bifurcation diagrams for \( x_n \) and \( y_n \) for \( b = 0.3, \; 1.0 < a < 1.5 \). Check if the values \( a = 1.01, 1.4 \) that we will use below correspond to stable periodic trajectories or chaotic behavior.

(b) Write a program in a file `attractor.f90` which will take \( NINIT = NL \times NL \) initial conditions \( (x_0(i), y_0(i)) \) \( i = 1, \ldots, NL \) on a \( NL \times NL \) lattice of the square \( x_m \leq x_0 \leq x_M, \; y_m \leq y_0 \leq y_M \). Each of the points \( (x_0(i), y_0(i)) \) will evolve according to equation \((3.45)\) for \( n = NSTEPS \) steps. The program will print the points \( (x_n(i), y_n(i)) \) to the stdout. Choose \( x_m = y_m = 0.6, \; x_M = y_M = 0.8, \; NL = 200 \).

(c) Choose \( a = 1.01, b = 0.3 \) and plot the points \( (x_n(i), y_n(i)) \) for \( n = 0, 1, 2, 3, 10, 20, 30, 40, 60, 1000 \) on the same diagram.

(d) Choose \( a = 1.4, b = 0.3 \) and plot the points \( (x_n(i), y_n(i)) \) for \( n = 0, \ldots, 7 \) on the same diagram.

(e) Choose \( a = 1.4, b = 0.3 \) and plot the points \( (x_n(i), y_n(i)) \) for \( n = 999 \) on the same diagram. Observe the Hénon strange attractor and its fractal properties. It is characterized by a Hausdorff\(^{12}\) dimension \( d_H = 1.261 \pm 0.003 \). Then magnify the regions

\[
\begin{align*}
\{(x, y)\} &\quad -1.290 < x < -1.270, \; 0.378 < y < 0.384 \\
\{(x, y)\} &\quad 1.150 < x < 1.130, \; 0.366 < y < 0.372 \\
\{(x, y)\} &\quad 0.108 < x < 0.114, \; 0.238 < y < 0.241 \\
\{(x, y)\} &\quad 0.300 < x < 0.320, \; 0.204 < y < 0.213 \\
\{(x, y)\} &\quad 1.076 < x < 1.084, \; 0.090 < y < 0.096 \\
\{(x, y)\} &\quad 1.216 < x < 1.226, \; 0.032 < y < 0.034
\end{align*}
\]

3.34 Consider the Duffing map:

\[
\begin{align*}
x_{n+1} &= y_n \\
y_{n+1} &= -bx_n + ay_n - y_n^3
\end{align*}
\]  

(a) Construct the two bifurcation diagrams for $x_n$ and $y_n$ for $b = 0.3$, $0 < a < 2.78$. Choose four different initial conditions $(x_0, y_0) = (\pm 1/\sqrt{2}, \pm 1/\sqrt{2})$. What do you observe?

(b) Use the program attractor.f90 from problem 33 in order to study the attractor of the map for $b = 0.3$, $a = 2.75$.

3.35 Consider the Tinkerbell map:

\[
\begin{align*}
x_{n+1} &= x_n^2 - y_n^2 + ax_n + by_n \\
y_{n+1} &= 2x_ny_n + cx_n + dy_n.
\end{align*}
\]

(a) Choose $a = 0.9$, $b = -0.6013$, $c = 2.0$, $d = 0.50$. Plot a trajectory on the plane by plotting the points $(x_n, y_n)$ for $n = 0, \ldots, 10000$ with $(x_0, y_0) = (-0.72, -0.64)$.

(b) Use the program attractor.f90 from problem 33 in order to study the attractor of the map for the values of the parameters $a$, $b$, $c$, $d$ given above. Choose $x_m = -0.68$, $x_M = -0.76$, $y_m = -0.60$, $y_M = -0.68$, $n = 10000$.

(c) Repeat the previous question by taking $d = 0.27$. 
Chapter 4

Motion of a Particle

In this chapter we will study the numerical solution of classical equations of motion of one dimensional mechanical systems, e.g. a point particle moving on the line, the simple pendulum etc. We will make an introduction to the numerical integration of ordinary differential equations with initial conditions and in particular to the Euler and Runge-Kutta methods. We study in detail the examples of the damped harmonic oscillator and of the damped pendulum under the influence of an external periodic force. The latter system is nonlinear and exhibits interesting chaotic behavior.

4.1 Numerical Integration of Newton’s Equations

Consider the problem of the solution of the dynamical equations of motion of one particle under the influence of a dynamical field given by Newton’s law. The equations can be written in the form

\[ \frac{d^2 \vec{x}}{dt^2} = \vec{a}(t, \vec{x}, \vec{v}), \]

where

\[ \vec{a}(t, \vec{x}, \vec{v}) = \vec{F} \quad \vec{v} = \frac{d\vec{x}}{dt}. \]

From the numerical analysis point of view, the problems that we will discuss are initial value problems for ordinary differential equations where the initial conditions

\[ \vec{x}(t_0) = \vec{x}_0 \quad \vec{v}(t_0) = \vec{v}_0, \]
determine a unique solution \( \ddot{x}(t) \). The equations (4.1) are of second order with respect to time and it is convenient to write them as a system of twice as many first order equations:

\[
\begin{align*}
\frac{d\ddot{x}}{dt} &= \ddot{v} \\
\frac{d\ddot{v}}{dt} &= \dddot{a}(t, \dddot{x}, \dddot{v}).
\end{align*}
\] (4.4)

In particular, we will be interested in the study of the motion of a particle moving on a line (1 dimension), therefore the above equations become

\[
\begin{align*}
\frac{dx}{dt} &= v \\
\frac{dv}{dt} &= a(t, x, v)
\end{align*}
\] 1-dimension

\[x(t_0) = x_0, \quad v(t_0) = v_0.\] (4.5)

When the particle moves on the plane (2 dimensions) the equations of motion become

\[
\begin{align*}
\frac{dx}{dt} &= v_x \\
\frac{dv_x}{dt} &= a_x(t, x, v_x, v_y) \\
\frac{dy}{dt} &= v_y \\
\frac{dv_y}{dt} &= a_y(t, x, v_x, v_y)
\end{align*}
\] 2-dimensions

\[x(t_0) = x_0, \quad v_x(t_0) = v_{0x}, \quad v_y(t_0) = v_{0y}.\] (4.6)

### 4.2 Prelude: Euler Methods

As a first attempt to tackle the problem, we will study a simple pendulum of length \( l \) in a homogeneous gravitational field \( g \) (figure 4.1). The equations of motion are given by the differential equations

\[
\begin{align*}
\frac{d^2\theta}{dt^2} &= -\frac{g}{l} \sin \theta \\
\frac{d\theta}{dt} &= \omega,
\end{align*}
\] (4.7)

which can be rewritten as a first order system of differential equations

\[
\begin{align*}
\frac{d\theta}{dt} &= \omega \\
\frac{d\omega}{dt} &= -\frac{g}{l} \sin \theta.
\end{align*}
\] (4.8)

The equations above need to be written in a discrete form appropriate for a numerical solution with the aid of a computer. We split the interval
4.2. PRELUDE: EULER METHODS

Figure 4.1: A simple pendulum of length \( l \) in a homogeneous gravitational field \( g \).

of time of integration \([t_i, t_f]\) to \( N - 1 \) equal intervals\(^1\) of width \( \Delta t \equiv h \), where \( h = (t_f - t_i)/(N - 1) \). The derivatives are approximated by the relations \((x_{n+1} - x_n)/\Delta t \approx x'_n\), so that

\[
\begin{align*}
\omega_{n+1} &= \omega_n + \alpha_n \Delta t \\
\theta_{n+1} &= \theta_n + \omega_n \Delta t.
\end{align*}
\]

(4.9)

where \( \alpha = -(g/l)\sin \theta \) is the angular acceleration. This is the so-called Euler method. The error at each step is estimated to be of order \((\Delta t)^2\). This is most easily seen by Taylor expanding around the point \( t_n \) and neglecting all terms starting from the second derivative and beyond\(^2\).

What we are mostly interested in is in the total error of the estimate of the functions we integrate for at time \( t_f \)? We expect that errors accumulate in an additive way at each integration step, and since the number of steps is \( N \propto 1/\Delta t \) the total error should be \( \propto (\Delta t)^2 \times (1/\Delta t) = \Delta t \). This is indeed what happens, and we say that Euler’s method is a first order method. Its range of applicability is limited and we only study it for academic reasons. Euler’s method is asymmetric because it uses information only from the beginning of the integration interval \((t, t + \Delta t)\). It can be put in a more balanced form by using the velocity at the end of the interval \((t, t + \Delta t)\). This way we obtain the Euler-Cromer method with a slightly

\(^1\)We have \( N \) discrete time points \( t_i \equiv t_1, \ldots, t_{N-1}, t_N \equiv t_f \)

\(^2\)See appendix 4.7 for retails.
improved behavior, but which is still of first order

\[
\begin{align*}
\omega_{n+1} &= \omega_n + \alpha_n \Delta t \\
\theta_{n+1} &= \theta_n + \omega_{n+1} \Delta t.
\end{align*}
\]  

(4.10)

An improved algorithm is the Euler–Verlet method which is of second order and gives total error $\| \sim (\Delta t)^2$. This is given by the equations

\[
\begin{align*}
\theta_{n+1} &= 2\theta_n - \theta_{n-1} + \alpha_n (\Delta t)^2 \\
\omega_n &= \frac{\theta_{n+1} - \theta_{n-1}}{2\Delta t}.
\end{align*}
\]  

(4.11)

The price that we have to pay is that we have to use a two step relation in order to advance the solution to the next step. This implies that we have to carefully determine the initial conditions of the problem which are given only at one given time $t_i$. We make one Euler time step backwards in order to define the value of $\theta_0$. If the initial conditions are $\theta_1 = \theta(t_i)$, $\omega_1 = \omega(t_i)$, then we define

\[
\theta_0 = \theta_1 - \omega_1 \Delta t + \frac{1}{2} \alpha_1 (\Delta t)^2.
\]  

(4.12)

\footnote{See appendix 4.7 for details.}

Figure 4.2: Convergence of Euler’s method for a simple pendulum with period $T \approx 1.987(\omega^2 = 10.0)$ for several values of the time step $\Delta t$ which is determined by the number of integration steps $N_t = 50—100,000$. The solution is given for $\theta_0 = 0.2$, $\omega_0 = 0.0$ and we compare it with the known solution for small angles with $\alpha(t) \approx -(g/l) \theta$.  

---

194  

CHAPTER 4. MOTION OF A PARTICLE
4.2. PRELUDE: EULER METHODS

It is important that at this step the error introduced is not larger than $O(\Delta t^2)$, otherwise it will spoil and eventually dominate the $O(\Delta t^2)$ total error of the method introduced by the intermediate steps. At the last step we also have to take

$$\omega_N = \frac{\theta_N - \theta_{N-1}}{\Delta t}. \quad (4.13)$$

Even though the method has smaller total error than the Euler method, it becomes unstable for small enough $\Delta t$ due to roundoff errors. In particular, the second equation in (4.11) gives the angular velocity as the ratio of two small numbers. The problem is that the numerator is the result of the subtraction of two almost equal numbers. For small enough $\Delta t$, this difference has to be computed from the last digits of the finite representation of the numbers $\theta_{n+1}$ and $\theta_n$ in the computer memory. The accuracy in the determination of $(\theta_{n+1} - \theta_n)$ decreases until it eventually becomes exactly zero. For the first equation of (4.11), the term $\alpha_n \Delta t^2$ is smaller by a factor $\Delta t$ compared to the term $\alpha_n \Delta t$ in Euler’s method. At some point, by decreasing $\Delta t$, we obtain $\alpha_n \Delta t^2 \ll 2\theta_n - \theta_{n-1}$ and the accuracy of the method vanishes due to the finite representation of real number in the memory of the computer. When the numbers $\alpha_n \Delta t^2$ and $2\theta_n - \theta_{n-1}$ differ from each other by more that approximately seven orders of magnitude, adding the first one to the second is equivalent to adding
zero and the contribution of the acceleration vanishes.\footnote{Numbers of type \texttt{real} have approximately seven significant digits. The accuracy of the operations described above is determined by the number $\epsilon$, which is the smallest positive number such that $1 + \epsilon > 1$. For a variable $x$ of some type, this number is given by a call to the Fortran intrinsic function \texttt{epsilon(x)}. For variables of type \texttt{real}, $\epsilon \approx 1.2 \times 10^{-7}$ and for variables of type \texttt{real(8)} $\epsilon \approx 2.2 \times 10^{-16}$.}

Writing programs that implement the methods discussed so far is quite simple. We will write a program that compares the results from all three methods Euler, Euler–Cromer and Euler–Verlet. The main program is mainly a user interface, and the computation is carried out by three subroutines \texttt{euler}, \texttt{euler_cromer} and \texttt{euler_verlet}. The user must provide the function \texttt{accel(x)} which gives the angular acceleration as a function of $x$. The variable $x$ in our problem corresponds to the angle $\theta$. For starters we take \texttt{accel(x) = -10.0 * sin(x)}; the acceleration of the simple pendulum.

The data structure is very simple: Three real arrays \texttt{REAL T(P), X(P) and V(P)} store the times $t_n$, the angles $\theta_n$ and the angular velocities $\omega_n$ for $n = 1, \ldots, Nt$. The user determines the time interval for the integration from $t_i = 0$ to $t_f = T_f$ and the number of discrete times $Nt$. The latter should be less than $P$, the size of the arrays. She also provides the initial conditions $\theta_0 = X_0$ and $\omega_0 = V_0$. After this, we call the main integration

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure4_4.png}
\caption{Convergence of the Euler-Verlet method, similarly to figure 4.2. We observe a faster convergence than Euler’s method, but the roundoff errors make the results useless for $Nt \gtrsim 50,000$ (note what happens when $Nt = 100,000$. Why?).}
\end{figure}
routines which take as input the initial conditions, the time interval of
the integration and the number of discrete times $X_{in}, V_{in}, T_{fi}, N_t$. The
output of the routines is the arrays $T, X, V$ which store the results for the
time, position and velocity respectively. The results are printed to the
files euler.dat, euler_cromer.dat and euler_verlet.dat.

After setting the initial conditions and computing the time step $\Delta t \equiv
h = T_{fi}/(N_t - 1)$, the integration in each of the subroutines is performed
in do loops which advance the solution for time $\Delta t$. The results are
stored at each step in the arrays $T, X, V$. For example, the central part of
the program for Euler’s method is:

```plaintext
T(1) = 0.0
X(1) = X_{in}
V(1) = V_{in}
\text{h} = T_{fi}/(N_t-1)
\text{do } i = 2, N_t
   T(i) = T(i-1) + h
   X(i) = X(i-1) + V(i-1)*h
   V(i) = V(i-1) + \text{accel}(X(i-1))*h
\text{enddo}
```

Some care has to be taken in the case of the Euler–Verlet method where
one has to initialize the first two steps, as well as take special care for the
Figure 4.6: Convergence of Euler-Cromer’s method, like in figure 4.5. We observe a faster convergence than for Euler’s method.

The full program can be found in the file euler.f90 and is listed below:

CHAPTER 4. MOTION OF A PARTICLE

The arrays \( T(1..Nt), X(1..Nt), V(1..Nt) \) which give \( x(t_i)=X(i), \frac{dx}{dt}(t_i)=V(i), t_i=T(i) \) \( i=1..Nt \) where for \( i=1 \) we have the initial condition.

```
subroutine euler_verlet(Xin,Vin,Tfi,Nt,T,X,V)
    implicit none
    integer :: Nt
    real, dimension(Nt):: T,X,V ! time t,x(t),v(t)=dx/dt
    real :: Xin,Vin,Tfi
    integer :: i
    real :: h,h2,X0,o2h
    real :: accel

    ! Initial conditions set here:
    T(1) = 0.0
    X(1) = Xin
    V(1) = Vin
    h = Tfi/(Nt-1) ! time step
    h2 = h*h ! time step squared
    o2h = 0.5/h ! h/2

    ! We have to initialize one more step: X0 corresponds to 'X(0)'
    X0 = X(1) - V(1) * h + accel(X(1)) * h2/2.0
    T(2) = h
    X(2) = 2.0*X(1) - X0 + accel(X(1)) * h2

    ! Now i starts from 3:
    do i = 3,Nt
        T(i) = T(i-1)+h
        X(i) = 2.0*X(i-1) - X(i-2) + accel(X(i-1))*h2
        V(i-1) = o2h * (X(i)-X(i-2))
        enddo

    ! Notice that we have one more step for the velocity:
    V(Nt)= (X(Nt)-X(Nt-1))/h
end subroutine euler_verlet
```

Compiling the running the program can be done with the commands:

```
> gfortran euler.f90 -o euler
> ./euler
Enter X_0,V_0,t_f,Nt (t_i=0):

2.4024025E-02 0.1995700 -4.7711499E-02
```
The last command shows the first 5 lines of the file euler.dat. We see the data for the time, the position and the velocity stored in 3 columns. We can graph the results using gnuplot:

```plaintext
gnuplot> plot "euler.dat" using 1:2 with lines
gnuplot> plot "euler.dat" using 1:3 with lines
```

These commands result in plotting the positions and the velocities as a function of time respectively. We can add the results of all methods to the last plot with the commands:

```plaintext
gnuplot> replot "euler_cromer.dat" using 1:3 with lines
gnuplot> replot "euler_verlet.dat" using 1:3 with lines
```

The results can be seen in figures 4.2–4.7. Euler’s method is unstable unless we take a quite small time step. The Euler–Cromer method behaves impressively better. The results converge and remain constant for \( Nt \approx 100,000 \). The Euler–Verlet method converges much faster, but roundoff errors kick in soon. This is more obvious in figure 4.7 where the initial angular position is large. For small angles we can compare with the solution one obtains for the harmonic pendulum (\( \sin(\theta) \approx \theta \)):

\[
\begin{align*}
\alpha(\theta) &= -\frac{g}{l} \theta \equiv -\omega^2 \theta \\
\theta(t) &= \theta_0 \cos(\Omega t) + \left( \frac{\omega_0}{\Omega} \right) \sin(\Omega t) \\
\omega(t) &= \omega_0 \cos(\Omega t) - \left( \frac{\theta_0 \Omega}{\omega_0} \right) \sin(\Omega t). \tag{4.14}
\end{align*}
\]

In figures 4.2–4.4 we observe that the results agree with the above formulas for the values of \( \Delta t \) where the methods converge. This way we can check our program for bugs. The plot of the functions above can be done with the following gnuplot commands:

```plaintext
gnuplot> set dummy t
gnuplot> omega2 = 10
gnuplot> X0 = 0.2
gnuplot> V0 = 0.0
gnuplot> omega = sqrt(omega2)
gnuplot> x(t) = X0 * cos(omega * t) + (V0/omega)*sin(omega*t)
gnuplot> v(t) = V0 * cos(omega * t) - (omega*X0)*sin(omega*t)
gnuplot> plot x(t), v(t)
```

\(^{5}\)The command set dummy t sets the independent variable for functions to be \( t \) instead of \( x \) which is the default.
The results should not be compared only graphically since subtle differences can remain unnoticed. It is more desirable to plot the differences of the theoretical values from the numerically computed ones which can be done using the commands:

```
plot "euler.dat" using 1:($2-x($1)) with lines
plot "euler.dat" using 1:($3-v($1)) with lines
```

The command using $1:($2-x($1))$ puts the values found in the first column on the $x$ axis and the value found in the second column minus the value of the function $x(t)$ for $t$ equal to the value found in the first column on the $y$ axis. This way, we can make the plots shown in figures 4.11-4.14.

### 4.3 Runge–Kutta Methods

Euler’s method is a one step finite difference method of first order. First order means that the total error introduced by the discretization of the integration interval $[t_i, t_f]$ by $N$ discrete times is of order $\sim O(h)$, where $h \equiv \Delta t = (t_f - t_i)/N$ is the time step of the integration. In this section we will discuss a generalization of this approach where the total error will be of higher order in $h$. This is the class of Runge-Kutta methods which are one step algorithms where the total discretization error is of order $\sim O(h^p)$. The local error introduced at each step is of order $O(h^{p+1})$ leading after $N = (t_f - t_i)/\Delta t$ steps to a maximum error of order

\[
\sim O(h^{p+1}) \times N = O(h^{p+1}) \times \frac{t_f - t_i}{\Delta t} \sim O(h^{p+1}) \times \frac{1}{h} = O(h^p). \tag{4.15}
\]

In such a case we say that we have a Runge-Kutta method of $p^{th}$ order. The price one has to pay for the increased accuracy is the evaluation of the derivatives of the functions in more than one points in the interval $(t, t + \Delta t)$.

Let’s consider for simplicity the problem with only one unknown function $x(t)$ which evolves in time according to the differential equation:

\[
\frac{dx}{dt} = f(t, x). \tag{4.16}
\]

Consider the first order method first. The most naive approach would

---

4 A small modification is necessary in order to plot the absolute value of the differences.
be to take the derivative to be given by the finite difference

\[ \frac{dx}{dt} \approx \frac{x_{n+1} - x_n}{\Delta t} = f(t_n, x_n) \Rightarrow x_{n+1} = x_n + h f(t_n, x_n). \]  

(4.17)

By Taylor expanding, we see that the error at each step is \( \mathcal{O}(h^2) \), therefore the error after integrating from \( t_i \rightarrow t_f \) is \( \mathcal{O}(h) \). Indeed,

\[ x_{n+1} = x(t_n + h) = x_n + h \frac{dx}{dt}(x_n) + \mathcal{O}(h^2) = x_n + h f(t_n, x_n) + \mathcal{O}(h^2). \]  

(4.18)

The geometry of the step is shown in figure 4.8. We start from point 1 and by linearly extrapolating in the direction of the derivative \( k_1 \equiv f(t_n, x_n) \) we determine the point \( x_{n+1} \).

We can improve the method above by introducing an intermediate point 2. This process is depicted in figure 4.9. We take the point 2 in the middle of the interval \( (t_n, t_{n+1}) \) by making a linear extrapolation from \( x_n \) in the direction of the derivative \( k_1 \equiv f(t_n, x_n) \). Then we use the slope at point 2 as an estimator of the derivative within this interval, i.e. \( k_2 \equiv f(t_{n+1/2}, x_{n+1/2}) = f(t_n + h/2, x_n + (h/2)k_1) \). We use \( k_2 \) to linearly

Figure 4.8: The geometry of the step of the Runge-Kutta method of 1st order given by equation (4.17).
extrapolate from $x_n$ to $x_{n+1}$. Summarizing, we have that

$$
k_1 &= f(t_n, x_n) \\
k_2 &= f(t_n + \frac{h}{2}, x_n + \frac{h}{2} k_1) \\
x_{n+1} &= x_n + hk_2.
$$

For the procedure described above we have to evaluate $f$ twice at each step, thereby doubling the computational effort. The error at each step (4.19) becomes $\sim O(h^3)$, however, giving a total error of $\sim O(h^2) \sim O(1/N^2)$. So for given computational time, (4.19) is superior to (4.17).

We can further improve the accuracy gain by using the Runge–Kutta method of 4th order. In this case we have 4 evaluations of the derivative $f$ per step, but the total error becomes now $\sim O(h^4)$ and the method is superior to that of (4.19)\footnote{Not always though! Higher order does not necessarily mean higher accuracy, although this is true in the simple cases considered here.}. The process followed is explained geometrically in figure 4.10. We use 3 intermediate points for evolving the solution from $x_n$ to $x_{n+1}$. Point 2 is determined by linearly extrapolating from $x_n$
to the midpoint of the interval \((t_n, t_{n+1}) = (t_n + h)\) by using the direction given by the derivative \(k_1 \equiv f(t_n, x_n)\), i.e. \(x_2 = x_n + (h/2)k_1\). We calculate the derivative \(k_2 \equiv f(t_n + h/2, x_n + (h/2)k_1)\) at the point 2 and we use it in order to determine point 3, also located at the midpoint of the interval \((t_n, t_{n+1})\). Then we calculate the derivative \(k_3 \equiv f(t_n + h/2, x_n + (h/2)k_2)\) at the point 3 and we use it to linearly extrapolate to the end of the interval \((t_n, t_{n+1})\), thereby obtaining point 4, i.e. \(x_4 = x_n + hk_3\). Then we calculate the derivative \(k_4 \equiv f(t_n + h, x_n + hk_3)\) at the point 4, and we use all four derivative \(k_1, k_2, k_3\) and \(k_4\) as estimators of the derivative of the function in the interval \((t_n, t_{n+1})\). If each derivative contributes with a particular weight in this estimate, the discretization error can become
\( \sim \mathcal{O}(h^5) \). Such a choice is

\[
\begin{align*}
k_1 &= f(t_n, x_n) \\
k_2 &= f(t_n + \frac{h}{2}, x_n + \frac{h}{2} k_1) \\
k_3 &= f(t_n + \frac{h}{2}, x_n + \frac{h}{2} k_2) \\
k_4 &= f(t_n + h, x_n + h k_3) \\
x_{n+1} &= x_n + \frac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4).
\end{align*}
\] (4.20)

We note that the second term of the last equation takes an average of the four derivatives with weights \( \frac{1}{6}, \frac{1}{3}, \frac{1}{3} \) and \( \frac{1}{6} \) respectively. A generic small change in these values will increase the discretization error to worse than \( h^5 \).

We remind to the reader the fact that by decreasing \( h \) the discretization errors decrease, but that roundoff errors will start showing up for small enough \( h \). Therefore, a careful determination of \( h \) that minimizes the total error should be made by studying the dependence of the results as a function of \( h \).

### 4.3.1 A Program for the 4th Order Runge–Kutta

Consider the problem of the motion of a particle in one dimension. For this, we have to integrate a system of two differential equations (4.5) for two unknown functions of time \( x_1(t) \equiv x(t) \) and \( x_2(t) \equiv v(t) \) so that

\[
\begin{align*}
\frac{dx_1}{dt} &= f_1(t, x_1, x_2) \\
\frac{dx_2}{dt} &= f_2(t, x_1, x_2)
\end{align*}
\] (4.21)
In this case, equations (4.20) generalize to:

\[
\begin{align*}
  k_{11} &= f_1(t_n, x_{1,n}, x_{2,n}) \\
  k_{21} &= f_2(t_n, x_{1,n}, x_{2,n}) \\
  k_{12} &= f_1(t_n + \frac{h}{2}, x_{1,n} + \frac{h}{2} k_{11}, x_{2,n} + \frac{h}{2} k_{21}) \\
  k_{22} &= f_2(t_n + \frac{h}{2}, x_{1,n} + \frac{h}{2} k_{12}, x_{2,n} + \frac{h}{2} k_{22}) \\
  k_{13} &= f_1(t_n + h, x_{1,n} + h k_{12}, x_{2,n} + h k_{22}) \\
  k_{23} &= f_2(t_n + h, x_{1,n} + h k_{13}, x_{2,n} + h k_{23}) \\
  k_{14} &= f_1(t_n + h, x_{1,n} + h k_{13}, x_{2,n} + h k_{23}) \\
  k_{24} &= f_2(t_n + h, x_{1,n} + h k_{14}, x_{2,n} + h k_{24}) \\
  x_{1,n+1} &= x_{1,n} + \frac{h}{6} (k_{11} + 2k_{12} + 2k_{13} + k_{14}) \\
  x_{2,n+1} &= x_{2,n} + \frac{h}{6} (k_{21} + 2k_{22} + 2k_{23} + k_{24}).
\end{align*}
\]

(4.22)

Programming this algorithm is quite simple. The main program is an interface between the user and the driver routine of the integration. The user enters the initial and final times \(t_i = T_i\) and \(t_f = T_f\) and the number of discrete time points \(N_t\). The initial conditions are \(x_1(t_i) = X_{10}\), \(x_2(t_i) = X_{20}\). The main data structure consists of three real arrays \(T(P)\), \(X1(P)\), \(X2(P)\) which store the times \(t_i = t_1, t_2, \ldots, t_{N_t} \equiv t_f\) and the corresponding values of the functions \(x_1(t_k)\) and \(x_2(t_k)\), \(k = 1, \ldots, N_t\). The main program calls the driver routine \(RK(T, X1, X2, T_i, T_f, X10, X20, N_t)\) which “drives” the heart of the program, the subroutine \(RKSTEP(t, x1, x2, dt)\) which performs one integration step using equations (4.22). \(RKSTEP\) evolves the functions \(x1\), \(x2\) at time \(t\) by one step \(h = dt\). The routine \(RK\) stores the calculated values in the arrays \(T\), \(X1\) and \(X2\) at each step. When \(RK\) returns the control to the main program, all the results are stored in \(T\), \(X1\) and \(X2\), which are subsequently printed in the file \(rk.dat\). The full program is listed below and can be found in the file \(rk.f90\):

4.4 Comparison of the Methods

Figure 4.11: The discrepancy of the numerical results of the Euler method from the analytic solution for the simple harmonic oscillator. The parameters chosen are $\omega^2 = 10$, $t_i = 0$, $t_f = 6$, $x(0) = 0.2$, $v(0) = 0$ and the number of steps is $N = 50, 500, 5000, 50000$. Observe that the error becomes approximately ten times smaller each time according to the expectation of being of order $O(\Delta t)$.

In this section we will check our programs for correctness and accuracy w.r.t. discretization and roundoff errors. The simplest test is to
check the results against a known analytic solution of a simple model. This will be done for the simple harmonic oscillator. Our programs will need small changes which are summarized below. First, we will need to use higher accuracy variables and we will change all variables of type REAL to REAL(8). For this we need to change the corresponding declarations in the beginning of each (sub)program. For each numerical constant in the program we need to put an explicit exponent with the letter D instead of an E. For example $0.5 \rightarrow 0.5D0, \ 1.2E-3 \rightarrow 1.2D-3$ etc. Then we need to alter the functions that compute the acceleration of the particle to give $a = -\omega^2 x$. We will take $\omega^2 = 10 \ (T \approx 1.987)$. Therefore the relevant part of the program in euler.f90 becomes

```fortran
real(8) function accel(x)
  implicit none
  real(8) :: x
  accel = -10.0D0*x
end function accel
```

and that of the program in rk.f90 becomes

```fortran
real(8) function f2(t,x1,x2)
  implicit none
```

Figure 4.12: Like in figure 4.11 for the Euler-Cromer method. The error becomes approximately ten times smaller each time according to the expectation of being of order $\mathcal{O}(\Delta t)$.
Like in figure 4.11 for the Euler-Verlet method. The error becomes approximately 100 times smaller each time according to the expectation of being of order $O(\Delta t^2)$.

The programs are run for a given time interval $t_i = 0$ to $t_f = 6$ with the initial conditions $x_0 = 0.2$, $v_0 = 0$. The time step $\Delta t$ is varied by varying the number of steps $\Delta t^{-1}$. The computed numerical solution is compared to the well known solution for the simple harmonic oscillator

\begin{align*}
a(x) &= -\omega^2 x \\
x_h(t) &= x_0 \cos(\omega t) + (v_0/\omega) \sin(\omega t) \\
v_h(t) &= v_0 \cos(\omega t) - (x_0\omega) \sin(\omega t)
\end{align*}

(4.23)

We study the deviation $\delta x(t) = |x(t) - x_h(t)|$ and $\delta v(t) = |v(t) - v_h(t)|$ as a function of the time step $\Delta t$. The results are shown in figures 4.11–4.14.

We note that for the Euler method and the Euler–Cromer method, the errors are of order $O(\Delta t)$ as expected. However, the latter has smaller errors compared to the first one. For the Euler–Verlet method, the error turns out to be of order $O(\Delta t^2)$ whereas for the 4th order Runge–Kutta is of order $O(\Delta t^4)$.

*The reader should confirm these claims, initially by looking at the figures 4.11–4.14 and then by reproducing these results. A particular time $t$ can be chosen and the errors can be plotted against $\Delta t$, $\Delta t^2$ and $\Delta t^4$ respectively.*
4.5. THE FORCED DAMPED OSCILLATOR

Figure 4.14: Like in figure 4.11 for the 4th order Runge–Kutta method. The error becomes approximately $10^{-4}$ times smaller each time according to the expectation of being of order $\sim \mathcal{O}(\Delta t^4)$. The roundoff errors become apparent for 50,000 steps.

Another way for checking the numerical results is by looking at a conserved quantity, like the energy, momentum or angular momentum, and study its deviation from its original value. In our case we study the mechanical energy

$$E = \frac{1}{2} m v^2 + \frac{1}{2} m \omega^2 x^2$$

which is computed at each step. The deviation $\delta E = |E - E_0|$ is shown in figures 4.15–4.18.

4.5 The Forced Damped Oscillator

In this section we will study a simple harmonic oscillator subject to a damping force proportional to its velocity and an external periodic driving force, which for simplicity will be taken to have a sinusoidal dependence in time,

$$\frac{d^2 x}{dt^2} + \gamma \frac{dx}{dt} + \omega_0^2 x = a_0 \sin \omega t,$$  

where $F(t) = m a_0 \sin \omega t$ and $\omega$ is the angular frequency of the driving force.
Consider initially the system without the influence of the driving force, i.e. with $a_0 = 0$. The real solutions of the differential equation which are finite for $t \to +\infty$ are given by

$$x_0(t) = c_1 e^{-(\gamma + \sqrt{\gamma^2 - 4\omega_0^2})t/2} + c_2 e^{-(\gamma - \sqrt{\gamma^2 - 4\omega_0^2})t/2}, \quad \gamma^2 - 4\omega_0^2 > 0,$$

(4.26)

$$x_0(t) = c_1 e^{-\gamma t/2} + c_2 e^{-\gamma t/2} t, \quad \gamma^2 - 4\omega_0^2 = 0,$$

(4.27)

$$x_0(t) = c_1 e^{-\gamma t/2} \cos \left( \sqrt{-\gamma^2 + 4\omega_0^2} t/2 \right)$$

$$+ c_2 e^{-\gamma t/2} \sin \left( \sqrt{-\gamma^2 + 4\omega_0^2} t/2 \right), \quad \gamma^2 - 4\omega_0^2 < 0.$$  

(4.28)

In the last case, the solution oscillates with an amplitude decreasing exponentially with time.

In the $a_0 > 0$ case, the general solution is obtained from the sum of a special solution $x_s(t)$ and the solution of the homogeneous equation $x_0(t)$. A special solution can be obtained from the ansatz $x_s(t) = A \sin \omega t +$
4.5. THE FORCED DAMPED OSCILLATOR

Figure 4.16: Like in figure 4.11 for the case of mechanical energy for the Euler–Cromer method.

\[ B \cos \omega t, \quad \text{which when substituted in (4.25) and solved for } A \text{ and } B \text{ we find that} \]

\[ x_s(t) = \frac{a_0 \left[ (\omega_0^2 - \omega^2) \cos \omega t + \gamma \omega \sin \omega t \right]}{(\omega_0^2 - \omega^2)^2 + \omega^2 \gamma^2}, \quad (4.29) \]

and

\[ x(t) = x_0(t) + x_s(t). \quad (4.30) \]

The solution \( x_0(t) \) decreases exponentially with time and eventually only \( x_s(t) \) remains. The only case where this is not true, is when we have resonance without damping for \( \omega = \omega_0, \gamma = 0 \). In that case the solution is

\[ x(t) = c_1 \cos \omega t + c_2 \sin \omega t + \frac{a_0}{4\omega^2} \left( \cos \omega t + 2(\omega t) \sin \omega t \right). \quad (4.31) \]

The first two terms are the same as that of the simple harmonic oscillator. The last one increases the amplitude linearly with time, which is a result of the influx of energy from the external force to the oscillator.

Our program will be a simple modification of the program in rk.f90. The main routines \( \text{RK}(T, X_1, X_2, T_0, T_F, X_{10}, X_{20}, N_t) \) and \( \text{RKSTEP}(t, x_1, x_2, dt) \) remain as they are. We only change the user interface. The basic parameters \( \omega_0, \omega, \gamma, a_0 \) are entered interactively by the user from the standard input stdin. These parameters should be accessible also by the function \( f2(t, x_1, x_2) \), and one way to be able to do this, is to store them in variables which are placed in a common block. Such variables are accessible to
all subprograms that declare a common block with the same name using a COMMON declaration. Such a declaration is shown in the following lines:

```fortran
real(8) :: omega_0, omega, gamma, a_0, omega_02, omega2
common /params/omega_0, omega, gamma, a_0, omega_02, omega2
```

which when written in a (sub)program, the (sub)program gains access to the “memory position” params where the values of the variables are stored. Another point that needs our attention is the function $f_2(t, x_1, x_2)$ which now takes the velocity $v \rightarrow x_2$ in its arguments:

```fortran
real(8) function f2(t, x1, x2)
  implicit none
  real(8) :: omega_0, omega, gamma, a_0, omega_02, omega2
  common /params/omega_0, omega, gamma, a_0, omega_02, omega2
  real(8) t, x1, x2, a
  a = a_0 * cos(omega * t)
  f2 = -omega_02 * x1 - gamma * x2 + a
end function f2
```

The main program found in the file dlo.f90 is listed below. The subroutines RK, RKSTEP are the same as in rk.f90 and should also be included in the same file.
Figure 4.18: Like in figure 4.11 for the case of mechanical energy for the 4th order Runge–Kutta method. Roundoff errors appear for large enough number of steps.

The results are shown in figures 4.19–4.22. Figure 4.19 shows the transition from a damped motion for \( \gamma > 2\omega_0 \) to an oscillating motion with damping amplitude for \( \gamma < 2\omega_0 \). The exponential decrease of the amplitude is shown in figure 4.21, whereas the dependence of the period \( T \) from the damping coefficient \( \gamma \) is shown in figure 4.22. Motivated by equation (4.28), written in the form

\[
4\omega_0^2 - \left( \frac{2\pi}{T} \right)^2 = \gamma^2, \tag{4.32}
\]

we construct the plot in figure 4.22. The right hand side of the equation is put on the horizontal axis, whereas the left hand side on the vertical. Equation (4.32) predicts that both quantities are equal and all measurements should lie on a particular line, the diagonal \( y = x \). The period \( T \)
can be estimated from the time between two consecutive extrema of $x(t)$ or two consecutive zeros of the velocity $v(t)$ (see figure 4.19).

Finally it is important to study the trajectory of the system in phase space. This can be seen in figure 4.20. A point in this space is a state of the system and a trajectory describes the evolution of the system’s states in time. We see that all such trajectories end up as $t \to +\infty$ to the point $(0, 0)$, independently of the initial conditions. Such a point is an example of a system’s attractor.

Next, we add the external force and study the response of the system to it. The system exhibits a transient behavior that depends on the initial conditions. For large enough times it approaches a steady state that does not depend on (almost all of) the initial conditions. This can be seen in figure 4.23. This is easily understood for our system by looking at equations (4.26)–(4.28). We see that the steady state $x_s(t)$ becomes dominant when the exponentials have damped away. $x_s(t)$ can be written in the form

$$x(t) = x_0(\omega) \cos(\omega t + \delta(\omega))$$

$$x_0(\omega) = \frac{a_0}{\sqrt{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2 \omega^2}}, \quad \tan \delta(\omega) = \frac{\omega - \omega_0}{\omega^2 - \omega_0^2}. \quad (4.33)$$

To be precise, phase space is the space of positions-momenta, but in our case the difference is trivial.
Figure 4.20: The phase space trajectory for the damped oscillator for several values of $\gamma$ and $\omega_0 = 3.145$. Note the attractor at $(x, v) = (0, 0)$ where all trajectories are “attracted to” as $t \to +\infty$.

These equations are verified in figure 4.24 where we study the dependence of the amplitude $x_0(\omega)$ on the angular frequency of the driving force. Finally we study the trajectory of the system in phase space. As we can see in figure 4.20, this time the attractor is an ellipse, which is a one dimensional curve instead of a zero dimensional point. For large enough times, all trajectories approach their attractor asymptotically.

4.6 The Forced Damped Pendulum

In this section we will study a non-linear dynamical system which exhibits interesting chaotic behavior. This is a simple model which, despite its deterministic nature, the prediction of its future behavior becomes intractable after a short period of time. Consider a simple pendulum in a constant gravitational field whose motion is damped by a force proportional to its velocity and it is under the influence of a vertical, harmonic external driving force:

$$\frac{d^2\theta}{dt^2} + \gamma \frac{d\theta}{dt} + \omega_0^2 \sin \theta = -2A \cos \omega t \sin \theta. \quad (4.34)$$
In the equation above, $\theta$ is the angle of the pendulum with the vertical axis, $\gamma$ is the damping coefficient, $\omega_0^2 = g/L$ is the pendulum’s natural angular frequency, $\omega$ is the angular frequency of the driving force and $2A$ is the amplitude of the external angular acceleration caused by the driving force.

In the absence of the driving force, the damping coefficient drives the system to the point $(\theta, \dot{\theta}) = (0, 0)$, which is an attractor for the system. This continues to happen for small enough $A$, but for $A > A_c$ the behavior of the system becomes more complicated.

The program that integrates the equations of motion of the system can be obtained by making trivial changes to the program in the file dlo.f90. This changes are listed in detail below, but we note that $X1 \leftrightarrow \theta$, $X2 \leftrightarrow \dot{\theta}$, $a_\theta \leftrightarrow A$. The final program can be found in the file fdp.f90. It is listed below, with the understanding that the commands in between the dots are the same as in the programs found in the files dlo.f90, rk.f90.

4.6. **THE FORCED DAMPED PENDULUM**

Figure 4.23: The period of oscillation for the forced damped oscillator for different initial conditions. We have chosen $\omega_0 = 3.145$, $\omega = 2.0$, $\gamma = 0.5$ and $a_0 = 1.0$. We note that after the transient behavior the system oscillates harmonically according to the relation $x(t) = x_0(\omega)\cos(\omega t + \delta)$.

```fortran
real(8) parameter :: pi = 3.14159265358979324D0
real(8) parameter :: pi2 = 6.28318530717958648D0

............................
x1 = x1 + h6 * (k11 + 2.0D0 * (k12 + k13) + k14)
x2 = x2 + h6 * (k21 + 2.0D0 * (k22 + k23) + k24)
if (x1 .gt. pi) x1 = x1 - pi2
if (x1 .lt. -pi) x1 = x1 + pi2
end subroutine RKSTEP
```

The final lines in the program are added so that the angle is kept within the interval $[-\pi, \pi]$.

In order to study the system’s properties we will set $\omega_0 = 1$, $\omega = 2$, and $\gamma = 0.2$ unless we explicitly state otherwise. The natural period of the pendulum is $T_0 = 2\pi / \omega_0 = 2\pi \approx 6.28318530717958648$ whereas that of the driving force is $T = 2\pi / \omega = \pi \approx 3.14159265358979324$. For $A < A_c$, with $A_c \approx 0.18$, the point $(\theta, \dot{\theta}) = (0, 0)$ is an attractor, which means that the pendulum eventually stops at its stable equilibrium point. For $A_c < A < 0.71$ the attractor is a closed curve, which means that the pendulum at its steady state oscillates indefinitely without circling.
Figure 4.24: The oscillation amplitude $x_0(\omega)$ as a function of $\omega$ for the forced damped oscillator, where $\omega_0 = 3.145$, $\gamma = 0.5$ and $a_0 = 1.0$. We observe a resonance for $\omega \approx \omega_0$. The points of the plot are our measurements and the line is the theoretical prediction given by equation (4.33).

through its unstable equilibrium point at $\theta = \pm \pi$. The period of motion is found to be twice that of the driving force. For $0.72 < A < 0.79$ the attractor is an open curve, because at its steady state the pendulum crosses the $\theta = \pm \pi$ point. The period of the motion becomes equal to that of the driving force. For $0.79 < A \lesssim 1.033$ we have period doubling for critical values of $A$, but the trajectory is still periodic. For even larger values of $A$ the system enters into a chaotic regime where the trajectories are non periodic. For $A \approx 3.1$ we find the system in a periodic steady state again, whereas for $A \approx 3.8 - 4.448$ we have period doubling. For $A \approx 4.4489$ we enter into a chaotic regime again etc. These results can be seen in figures 4.27-4.29. The reader should construct the bifurcation diagram of the system by solving problem 20 of this chapter.

We can also use the so called Poincaré diagrams in order to study the chaotic behavior of a system. These are obtained by placing a point in phase space when the time is an integer multiple of the period of the driving force. Then, if for example the period of the motion is equal to that of the period of the driving force, the Poincaré diagram consists of only one point. If the period of the motion is an $n$–multiple of the
Figure 4.25: A phase space trajectory of the forced damped oscillator with $\omega_0 = 3.145$, $\omega = 2.0$, $\gamma = 0.5$ and $a_0 = 1.0$. The harmonic oscillation which is the steady state of the system is an ellipse, which is an attractor of all the phase space trajectories that correspond to different initial conditions.

period of the driving force then the Poincaré diagram consists of only $n$ points. Therefore, in the period doubling regime, the points of the Poincaré diagram double at each period doubling point. In the chaotic regime, the Poincaré diagram consists of an infinite number of points which belong to sets that have interesting fractal structure. One way to construct the Poincaré diagram numerically, is to process the data of the output file fdp.dat using awk:\n
```
awk -v o=$omega -v nt=$Nt -v tf=$TF \
  'BEGIN{T=6.283185307179/o; dt=tf/nt;} $1%T<dt{ print $2,$3}' \
fdp.dat
```

where $\omega$, $\text{Nt}$, $\text{TF}$ are the values of the angular frequency $\omega$, the number of points of time and the final time $t_f$. We calculate the period $T$ and the time step $dt$ in the program. Then we print those lines of the file

\[\text{The command can be written in one line without the final } \backslash \text{ of the first and second lines.}\]
where the time is an integer multiple of the period\[^3\]. This is accomplished by the modulo operation $1 \% T$. The value of the expression $1 \% T < dt$ is true when the remainder of the division of the first column ($1$) of the file $fdp.dat$ with the period $T$ is smaller than $dt$. The results in the chaotic regime are displayed in figure [4.30].

We close this section by discussing another concept that helps us in the analysis of the dynamical properties of the pendulum. This is the concept of the \textit{basin of attraction} which is the set of initial conditions in phase space that lead the system to a specific attractor. Take for example the case for $A > 0.79$ in the regime where the pendulum at its steady state has a circular trajectory with a positive or negative direction. By taking a large sample of initial conditions and recording the direction of the resulting motion after the transient behavior, we obtain figure [4.31].

\[^3\]The accuracy of this condition is limited by $dt$, which makes the points in the Poincaré diagram slightly fuzzy.
4.7 Appendix: On the Euler–Verlet Method

Equations (4.11) can be obtained from the Taylor expansion

\[
\theta(t + \Delta t) = \theta(t) + (\Delta t)\theta'(t) + \frac{(\Delta t)^2}{2!}\theta''(t) + \frac{(\Delta t)^3}{3!}\theta'''(t) + \mathcal{O}((\Delta t)^4)
\]

\[
\theta(t - \Delta t) = \theta(t) - (\Delta t)\theta'(t) + \frac{(\Delta t)^2}{2!}\theta''(t) - \frac{(\Delta t)^3}{3!}\theta'''(t) + \mathcal{O}((\Delta t)^4).
\]

By adding and subtracting the above equations we obtain

\[
\theta(t + \Delta t) + \theta(t - \Delta t) = 2\theta(t) + (\Delta t)^2\theta''(t) + \mathcal{O}((\Delta t)^4)
\]

\[
\theta(t + \Delta t) - \theta(t - \Delta t) = 2(\Delta t)\theta'(t) + \mathcal{O}((\Delta t)^3)
\]

which give equations (4.11)

\[
\theta(t + \Delta t) = 2\theta(t) - \theta(t - \Delta t) + (\Delta t)^2\alpha(t) + \mathcal{O}((\Delta t)^4)
\]

\[
\omega(t) = \frac{\theta(t + \Delta t) - \theta(t - \Delta t)}{2\Delta t} + \mathcal{O}((\Delta t)^3)
\]
From the first equation and equations (4.9) we obtain:

\[
\theta(t + \Delta t) = \theta(t) + \omega(t)(\Delta t) + O((\Delta t)^2)
\]  

(4.37)

When we perform a numerical integration, we are interested in the total error accumulated after \(N - 1\) integration steps. In this method, these errors must be studied carefully:

- The error in the velocity \(\omega(t)\) does not accumulate because it is given by the difference of the positions \(\theta(t + \Delta t) - \theta(t - \Delta t)\).

- The accumulation of the errors for the position is estimated as follows: Assume that \(\delta \theta(t)\) is the total accumulated error from the integration from time \(t_0\) to \(t\). Then according to the expansions

Figure 4.28: A phase space trajectory of the forced damped pendulum. The parameters chosen are \(\omega_0 = 1.0, \omega = 2.0, \gamma = 0.2\) and \(A = 1.031, 1.033, 1.04, 1.4\). We observe the chaotic behavior of the system.
Figure 4.29: A phase space trajectory of the forced damped pendulum. The parameters chosen are $\omega_0 = 1.0$, $\omega = 2.0$, $\gamma = 0.2$ and $A = 1.568, 3.8, 4.44, 4.5$. We observe the system exiting and reentering regimes of chaotic behavior.

\[ \frac{\Delta \theta(t_0 + \Delta t)}{\Delta t} = \frac{\Delta \theta(t_0 + 2\Delta t)}{2\Delta t} = \frac{\Delta \theta(t_0 + 3\Delta t)}{3\Delta t} \]

(4.36) the error for the first step is $\delta \theta(t_0 + \Delta t) = \mathcal{O}((\Delta t)^4)$. Then

\[
\begin{align*}
\theta(t_0 + 2\Delta t) &= 2\theta(t_0 + \Delta t) - \theta(t_0) + \Delta t^2 \alpha(t_0 + \Delta t) + \mathcal{O}((\Delta t)^4) \\
\delta \theta(t_0 + 2\Delta t) &= 2\delta \theta(t_0 + \Delta t) - \delta \theta(t_0) + \mathcal{O}((\Delta t)^4) \\
&= 2\mathcal{O}((\Delta t)^4) - 0 + \mathcal{O}((\Delta t)^4) \\
&= 3\mathcal{O}((\Delta t)^4).
\end{align*}
\]

For the next steps we obtain

\[
\begin{align*}
\theta(t_0 + 3\Delta t) &= 2\theta(t_0 + 2\Delta t) - \theta(t_0 + \Delta t) + \Delta t^2 \alpha(t_0 + 2\Delta t) + \mathcal{O}((\Delta t)^4) \\
\delta \theta(t_0 + 3\Delta t) &= 2\delta \theta(t_0 + 2\Delta t) - \delta \theta(t_0 + \Delta t) + \mathcal{O}((\Delta t)^4) \\
&= 6\mathcal{O}((\Delta t)^4) - \mathcal{O}((\Delta t)^4) + \mathcal{O}((\Delta t)^4) \\
&= 6\mathcal{O}((\Delta t)^4).
\end{align*}
\]

\[\text{Remember that the acceleration } \alpha(t) \text{ is given, therefore } \delta \alpha(t) = 0.\]
Figure 4.30: A Poincaré diagram for the forced damped pendulum in its chaotic regime. The parameters chosen are \( \omega_0 = 1.0, \omega = 2.0, \gamma = 0.2 \) and \( A = 1.4, 4.5 \).

Figure 4.31: Basin of attraction for the forced damped pendulum. The parameters chosen are \( \omega_0 = 1.0, \omega = 2.0, \gamma = 0.2 \) and \( A = 0.85, 1.4 \).

\[
\theta(t_0 + 4\Delta t) = 2\theta(t_0 + 3\Delta t) - \theta(t_0 + 2\Delta t) + \Delta t^2 \alpha(t_0 + 3\Delta t) + O((\Delta t)^4) \Rightarrow \\
\delta\theta(t_0 + 4\Delta t) = 2\delta\theta(t_0 + 3\Delta t) - \delta\theta(t_0 + 2\Delta t) + O((\Delta t)^4) \\
= 12O((\Delta t)^4) - 3O((\Delta t)^4) + O((\Delta t)^4) \\
= 10O((\Delta t)^4).
\]

Then, inductively, if \( \delta\theta(t_0 + (n - 1)\Delta t) = \frac{(n-1)n}{2}O((\Delta t)^4) \), we obtain

\[
\theta(t_0 + n\Delta t) = 2\theta(t_0 + (n - 1)\Delta t) - \theta(t_0 + (n - 2)\Delta t) + \Delta t^2 \alpha(t_0 + (n - 1)\Delta t) \\
+ O((\Delta t)^4) \Rightarrow \\
\delta\theta(t_0 + n\Delta t) = 2\delta\theta(t_0 + (n - 1)\Delta t) - \delta\theta(t_0 + (n - 2)\Delta t) + O((\Delta t)^4) \\
= 2 \left( \frac{(n-1)n}{2} O((\Delta t)^4) - \frac{(n-2)(n-1)}{2} O((\Delta t)^4) + O((\Delta t)^4) \right) \\
= \frac{n(n+1)}{2} O((\Delta t)^4).
\]
Finally
\[ \delta \theta(t_0 + n\Delta t) = \frac{n(n+1)}{2} O((\Delta t)^4) - \frac{1}{\Delta t^2} O((\Delta t)^4) \sim O((\Delta t)^2). \] (4.38)

Therefore the total error is \( O((\Delta t)^2) \).

We also mention the Velocity Verlet method or the Leapfrog method. In this case we use the velocity explicitly:

\[ \theta_{n+1} = \theta_n + \omega_n \Delta t + \frac{1}{2} \alpha_n \Delta t^2 \]
\[ \omega_n = \omega_{n+\frac{1}{2}} = \omega_n + \frac{1}{2} \alpha_n \Delta t \]
\[ \omega_{n+1} = \omega_{n+\frac{1}{2}} + \frac{1}{2} \alpha_{n+1} \Delta t. \] (4.39)

The last step uses the acceleration \( \alpha_{n+1} \) which should depend only on the position \( \theta_{n+1} \) and not on the velocity.

The Verlet methods are popular in molecular dynamics simulations of many body systems. One of their advantages is that the constraints of the system of particles are easily encoded in the algorithm.

### 4.8 Appendix: 2nd order Runge–Kutta Method

In this appendix we will show how the choice of the intermediate point 2 in equation (4.17) reduces the error by a power of \( h \). This choice is special, since by choosing another point (e.g. \( t = t_n + 0.4h \)) the result would have not been the same. Indeed, from the relation

\[ \frac{dx}{dt} = f(t, x) \Rightarrow x_{n+1} = x_n + \int_{t_n}^{t_{n+1}} f(t, x) \, dx. \] (4.40)

By Taylor expanding around the point \( (t_{n+1/2}, x_{n+1/2}) \) we obtain

\[ f(t, x) = f(t_{n+1/2}, x_{n+1/2}) + (t - t_{n+1/2}) \frac{df}{dt}(t_{n+1/2}) + O(h^2). \] (4.41)
Therefore

\[
\int_{t_n}^{t_{n+1}} f(t, x) \, dx = \begin{align*}
&= f(t_{n+1/2}, x_{n+1/2})(t_{n+1} - t_n) + \frac{df}{dt}(t_{n+1/2}) \left( \frac{(t - t_{n+1/2})^2}{2} t_{n+1} \right) \\
&\quad + \mathcal{O}(h^2)(t_{n+1} - t_n) \\
&= f(t_{n+1/2}, x_{n+1/2})h + \frac{df}{dt}(t_{n+1/2}) \left( \frac{(t_{n+1} - t_{n+1/2})^2}{2} - \frac{(t_n - t_{n+1/2})^2}{2} \right) \\
&\quad + \mathcal{O}(h^2)h \\
&= f(t_{n+1/2}, x_{n+1/2})h + \frac{df}{dt}(t_{n+1/2}) \left( \frac{h^2}{2} - \frac{(-h)^2}{2} \right) + \mathcal{O}(h^3) \\
&= f(t_{n+1/2}, x_{n+1/2})h + \mathcal{O}(h^3) .
\end{align*}
\] (4.42)

Note that for the vanishing of the \( \mathcal{O}(h) \) term it is necessary to place the intermediate point at time \( t_{n+1/2} \).

This is not a unique choice. This can be most easily seen by a different analysis of the Taylor expansion. Expanding around the point \( (t_n, x_n) \) we obtain

\[
x_{n+1} = x_n + (t_{n+1} - t_n) \frac{dx_n}{dt} + \frac{1}{2} \frac{d^2 x_n}{dt^2} + \mathcal{O}(h^3) \\
= x_n + hf_n + \frac{h^2}{2} \frac{df_n}{dt} + \mathcal{O}(h^3) \\
= x_n + hf_n + \frac{h^2}{2} \left( \frac{\partial f_n}{\partial t} + \frac{\partial f_n}{\partial x} \frac{dx_n}{dt} \right) + \mathcal{O}(h^3) \\
= x_n + hf_n + \frac{h^2}{2} \left( \frac{\partial f_n}{\partial t} + \frac{\partial f_n}{\partial x} f_n \right) + \mathcal{O}(h^3) ,
\] (4.43)

where we have set \( f_n \equiv f(t_n, x_n), \frac{dx_n}{dt} \equiv \frac{df}{dx}(x_n) \) etc. We define

\[
\begin{align*}
k_1 &= f(t_n, x_n) = f_n \\
k_2 &= f(t_n + ah, x_n + bhk_1) \\
x_{n+1} &= x_n + h(c_1k_1 + c_2k_2).
\end{align*}
\] (4.44)

and we will determine the conditions so that the terms \( \mathcal{O}(h^2) \) of the last equation in the error are identical with those of equation (4.43). By
expanding $k_2$ we obtain
\[
k_2 = f(t_n + ah, x_n + bhk_1) = f(t_n, x_n + bhk_1) + ha \frac{\partial f}{\partial t}(t_n, x_n + bhk_1) + \mathcal{O}(h^2)
\]
\[
= f(t_n, x_n) + hk_1 \frac{\partial f}{\partial x}(t_n, x_n) + ha \frac{\partial f}{\partial t}(t_n, x_n) + \mathcal{O}(h^2)
\]
\[
= f_n + h \left\{ a \frac{\partial f}{\partial t} + bk_1 \frac{\partial f_n}{\partial x} \right\} + \mathcal{O}(h^2)
\]
\[
= f_n + h \left\{ a \frac{\partial f_n}{\partial t} + bk_n \frac{\partial f_n}{\partial x} \right\} + \mathcal{O}(h^2) \quad \text{(4.45)}
\]

Substituting in (4.44) we obtain
\[
x_{n+1} = x_n + h(c_1k_1 + c_2k_2)
\]
\[
= x_n + h \left\{ c_1f_n + c_2f_n + c_2h \left( a \frac{\partial f_n}{\partial t} + bk_n \frac{\partial f_n}{\partial x} \right) + \mathcal{O}(h^2) \right\}
\]
\[
= x_n + h(c_1 + c_2)f_n + \frac{h^2}{2} \left( (2c_2a) \frac{\partial f_n}{\partial t} + (2c_2b) f_n \frac{\partial f_n}{\partial x} \right)
\]
\[
+ \mathcal{O}(h^3). \quad \text{(4.46)}
\]

All we need is to choose
\[
c_1 + c_2 = 1
\]
\[
2c_2a = 1
\]
\[
2c_2b = 1. \quad \text{(4.47)}
\]

The choice $c_1 = 0$, $c_2 = 1$, $a = b = 1/2$ leads to equation (4.19). Some other choices in the bibliography are $c_2 = 1/2$ and $c_2 = 3/4$. 
CHAPTER 4. MOTION OF A PARTICLE

4.9 Problems

4.1 Prove that the total error in the Euler–Cromer method is of order $\Delta t$.

4.2 Reproduce the results in figures 4.11–4.18.

4.3 Improve your programs so that there is no accumulation of roundoff error in the calculation of time when $h$ is very small for the methods Euler, Euler-Cromer, Euler-Verlet and Runge-Kutta. Repeat the analysis of the previous problem.

4.4 Make the appropriate changes in your programs of the Euler, Euler-Cromer, Euler-Verlet and Runge-Kutta methods so that all floating variables change from REAL$\rightarrow$REAL(8). Repeat the analysis of the previous problem.

4.5 Compare the results obtained from the Euler, Euler-Cromer, Euler-Verlet, Runge-Kutta methods for the following systems where the analytic solution is known:

(a) Particle falling in a constant gravitational field. Consider the case $v(0) = 0$, $m = 1$, $g = 10$.

(b) Particle falling in a constant gravitational field moving in a fluid from which exerts a force $F = -kv$ on the particle. Consider the case $v(0) = 0$, $m = 1$, $g = 10$ $k = 0.1, 1.0, 2.0$. Calculate the limiting velocity of the particle numerically and compare the value obtained to the theoretical expectation.

(c) Repeat for the case of a force of resistance of magnitude $|F| = kv^2$.

4.6 Consider the damped harmonic oscillator

$$\frac{d^2x}{dt^2} + \gamma \frac{dx}{dt} + \omega_0^2 x = 0.$$ (4.48)

Take $\omega_0 = 3.145$, $\gamma = 0.5$ and calculate its mechanical energy as a function of time. Is it monotonic? Why? (show that $d(E/m)/dt = -\gamma v^2$). Repeat for $\gamma = 4, 5, 6, 7, 8$. When is the system oscillating and when it’s not? Calculate numerically the critical value of $\gamma$ for which the system passes from a non oscillating to an oscillating regime. Compare your results with the theoretical expectations.
4.7 Reproduce the results of figures 4.19–4.22.

4.8 Reproduce the results of figures 4.23–4.26. Calculate the phase $\delta(\omega)$ numerically and compare with equation (4.33).

4.9 Consider a simple model for a swing. Take the damped harmonic oscillator and a driving force which periodically exerts a momentary push with angular frequency $\omega$. Define “momentary” to be an impulse given by the acceleration $a_0$ by an appropriately small time interval $\Delta t$. The acceleration is 0 for all other times. Calculate the amplitude $x_0(\omega)$ for $\omega_0 = 3.145$ and $\gamma = 0.5$.

4.10 Consider a “half sine” driving force on a damped harmonic oscillator

$$a(t) = \begin{cases} a_0 \cos \omega t & \cos \omega t > 0 \\ 0 & \cos \omega t \leq 0 \end{cases}$$

Study the transient behavior of the system for several initial conditions and calculate its steady state motion for $\omega_0 = 3.145$ and $\gamma = 0.5$. Calculate the amplitude $x_0(\omega)$.

4.11 Consider the driving force on a damped oscillator given by

$$a(t) = \frac{1}{\pi} + \frac{1}{2} \cos \omega + \frac{2}{3\pi} \cos 2\omega t - \frac{2}{15\pi} \cos 4\omega t$$

Study the transient behavior of the system for several initial conditions and calculate its steady state motion for $\omega_0 = 3.145$ and $\gamma = 0.5$. Calculate the amplitude $x_0(\omega)$. Compare your results with those of the previous problem and comment about.

4.12 Write a program that simulates $N$ identical, independent harmonic oscillators. Take $N = 20$ and choose random initial conditions for each one of them. Study their trajectories in phase space and check whether they cross each other. Comment on your results.

4.13 Place the $N = 20$ harmonic oscillators of the previous problem in a small square in phase space whose center is at the origin of the axes. Consider the evolution of the system in time. Does the shape of the rectangle change in time? Does the area change in time? Explain...

4.14 Repeat the previous problem when each oscillator is damped with $\gamma = 0.5$. Take $\omega_0 = 3.145$. 
4.15 Consider the forced damped oscillator with \( \omega = 2, \omega_0 = 1.0, \gamma = 0.2 \). Study the transient behavior of the system in the plots of \( \theta(t) \), \( \dot{\theta}(t) \) for \( A = 0.1, 0.5, 0.79, 0.85, 1.03, 1.4 \).

4.16 Consider the forced damped pendulum with \( \omega = 2, \omega_0 = 1.0, \gamma = 0.2 \) and study the phase space trajectories for \( A = 0.1, 0.19, 0.21, 0.25, 0.5, 0.71, 0.79, 0.85, 1.02, 1.031, 1.033, 1.05, 1.08, 1.1, 1.4, 1.8, 3.1, 3.5, 3.8, 4.2, 4.42, 4.44, 4.445, 4.447, 4.4488 \). Consider both the transient behavior and the steady state motion.

4.17 Reproduce the results in figures 4.30.

4.18 Reproduce the results in figures 4.31.

4.19 Consider the forced damped oscillator with

\[
\omega_0 = 1, \quad \omega = 2, \quad \gamma = 0.2
\]

After the transient behavior, the motion of the system for \( A = 0.60 \), \( A = 0.75 \) and \( A = 0.85 \) is periodic. Measure the period of the motion with an accuracy of three significant digits and compare it with the natural period of the pendulum and with the period of the driving force. Take as initial conditions the following pairs: \((\theta_0, \dot{\theta}_0) = (3.1, 0.0), (2.5, 0.0), (2.0, 0.0), (1.0, 0.0), (0.2, 0.0), (0.0, 1.0), (0.0, 3.0), (0.0, 6.0)\). Check if the period is independent of the initial conditions.

4.20 Consider the forced damped pendulum with

\[
\omega_0 = 1, \quad \omega = 2, \quad \gamma = 0.2
\]

Study the motion of the pendulum when the amplitude \( A \) takes values in the interval \([0.2, 5.0]\). Consider specific discrete values of \( A \) by splitting the interval above in subintervals of width equal to \( \delta A = 0.002 \). For each value of \( A \), record in a file the value of \( A \), the angular position and the angular velocity of the pendulum when \( t_k = k\pi \) with \( k = k_{\text{trans}}, k_{\text{trans}} + 1, k_{\text{trans}} + 2, \ldots, k_{\text{max}} \):

\[
A, \quad \theta(t_k), \quad \dot{\theta}(t_k)
\]

The choice of \( k_{\text{trans}} \) is made so that the transient behavior will be discarded and study only the steady state of the pendulum. You may take \( k_{\text{max}} = 500, k_{\text{trans}} = 400, t_i = 0, t_f = 500\pi \), and split the intervals \([t_k, t_k + \pi]\) to 50 subintervals. Choose \( \theta_0 = 3.1, \dot{\theta}_0 = 0 \).
(a) Construct the bifurcation diagram by plotting the points \((A, \theta(t_k))\).

(b) Repeat by plotting the points \((A, \dot{\theta}(t_k))\).

(c) Check whether your results depend on the choice of \(\theta_0, \dot{\theta}_0\). Repeat your analysis for \(\theta_0 = 0, \dot{\theta}_0 = 1\).

(d) Study the onset of chaos: Take \(A \in [1.0000, 1.0400]\) with \(\delta A = 0.0001\) and \(A \in [4.4300, 4.4500]\) with \(\delta A = 0.0001\) and compute with the given accuracy the value \(A_c\) where the system enters into the chaotic behavior regime.

(e) Plot the points \((\theta(t_k), \dot{\theta}(t_k))\) for \(A = 1.034, 1.040, 1.080, 1.400, 4.450, 4.600\). Put 2000 points for each value of \(A\) and comment on the strength of the chaotic behavior of the pendulum.
Chapter 5

Planar Motion

In this chapter we will study the motion of a particle moving on the plane under the influence of a dynamical field. Special emphasis will be given to the study of the motion in a central field, like in the problem of planetary motion and scattering. We also study the motion of two or more interacting particles moving on the plane, which requires the solution of a larger number of dynamical equations. These problems can be solved numerically by using Runge–Kutta integration methods, therefore this chapter extends and applies the numerical methods studied in the previous chapter.

5.1 Runge–Kutta for Planar Motion

In two dimensions, the initial value problem that we are interested in, is solving the system of equations (4.6)

\[
\begin{align*}
\frac{dx}{dt} &= v_x \\
\frac{dv_x}{dt} &= a_x(t, x, v_x, y, v_y) \\
\frac{dy}{dt} &= v_y \\
\frac{dv_y}{dt} &= a_y(t, x, v_x, y, v_y).
\end{align*}
\]  

(5.1)

The 4th order Runge-Kutta method can be programmed by making small modifications of the program in the file \texttt{rk.f90}. In order to facilitate the study of many different dynamical fields, for each field we put the code of the respective acceleration in a different file. The code which is common for all the forces, namely the user interface and the implementation of the Runge–Kutta method, will be put in the file \texttt{rk2.f90}. The program that computes the acceleration will be put in a file named \texttt{rk_XXX.f90}, where \texttt{XXX} is a string of characters that identifies the force.
For example, the file rk2_hoc.f90 contains the program computing the acceleration of the simple harmonic oscillator, the file rk2_g.f90 the acceleration of a constant gravitational field $\vec{g} = -g \hat{y}$ etc.

Different force fields will require the use of one or more coupling constants which need to be accessible to the code in the main program and some subroutines. For this reason, we will provide two variables $k_1$, $k_2$ in a common block:

```
real(8) :: k1, k2
common /couplings/ k1, k2
```

This common block will be accessed by the acceleration functions $f_3$ and $f_4$, the function energy and the main program where the user will enter the values of $k_1$ and $k_2$. The initial conditions are stored in the variables $X_{10}$ $\leftrightarrow x_0$, $X_{20}$ $\leftrightarrow y_0$, $V_{10}$ $\leftrightarrow v_x$, $V_{20}$ $\leftrightarrow v_y$, and the values of the functions of time will be stored in the arrays $X_{1}(P)$ $\leftrightarrow x(t)$, $X_{2}(P)$ $\leftrightarrow y(t)$, $V_{1}(P)$ $\leftrightarrow v_x(t)$, $V_{2}(P)$ $\leftrightarrow v_y(t)$. The integration is performed by a call to the subroutine

```
call RK(T, X1, X2, V1, V2, Ti, Tf, X_{10}, X_{20}, V_{10}, V_{20}, Nt)
```

The results are written to the file rk2.dat. Each line in this file contains the time, position, velocity and the total mechanical energy, where the energy is calculated by the function $\text{energy}(t,x_1,x_2,v_1,v_2)$:

```
open (unit=11, file='rk2.dat')
do i=1,Nt
   write (11,*) T(i), X1(i), X2(i), V1(i), V2(i), &
   energy(T(i), X1(i), X2(i), V1(i), V2(i))
endo
```

The code for the function $\text{energy}$, which is different for each force field, is written in the same file with the acceleration. The code for the subroutine $\text{RKSTEP}(t,x_1,x_2,x_3,x_4,dt)$ should be extended in order to integrate four instead of two functions. The full code is listed below:

```

end subroutine RKSTEP
\end{verbatim}
5.2 Projectile Motion

Consider a particle in the constant gravitational field near the surface of the earth which moves with constant acceleration $\vec{g} = -g \hat{y}$ so that

$$
\begin{align*}
    x(t) &= x_0 + v_{0x} t \\
    v_x(t) &= v_{0x} \\
    a_x(t) &= 0
\end{align*}
$$

$$
\begin{align*}
    y(t) &= y_0 + v_{0y} t - \frac{1}{2} g t^2 \\
    v_y(t) &= v_{0y} - gt \\
    a_y(t) &= -g
\end{align*}
$$

(5.2)

The particle moves on a parabolic trajectory that depends on the initial conditions

$$
(y - y_0) = \left( \frac{v_{0y}}{v_{0x}} \right) (x - x_0) - \frac{1}{2} \frac{g}{v_{0x}^2} (x - x_0)^2
$$

$$
= \tan \theta (x - x_0) - \frac{\tan^2 \theta}{4h_{\text{max}}} (x - x_0)^2,
$$

(5.3)

where $\tan \theta = v_{0y}/v_{0x}$ is the direction of the initial velocity and $h_{\text{max}}$ is the maximum height of the trajectory.

The acceleration $a_x(t) = 0$ $a_y(t) = -g$ $(a_x \leftrightarrow f3, a_y \leftrightarrow f4)$ and the mechanical energy is coded in the file rk2_g.f90:

```fortran
! --------------------------------------------------------------
! The acceleration functions f3, f4(t,x1,x2,v1,v2) provided
! by the user
! --------------------------------------------------------------
!
! Free fall in constant gravitational field with
! g = -k2
!
real(8) function f3(t,x1,x2,v1,v2)
    implicit none
    real(8) :: t,x1,x2,v1,v2
    common /couplings/k1,k2
!
    f3=0.0D0 !dx3/dt=dv1/dt=a1
end function f3
!
!
real(8) function f4(t,x1,x2,v1,v2)
    implicit none
    real(8) :: t,x1,x2,v1,v2
!
end subroutine RKSTEP
```
5.2. PROJECTILE MOTION

Figure 5.1: Plots of $x(t)$, $y(t)$, $v_x(t)$, $v_y(t)$ for a projectile fired in a constant gravitational field $\vec{g} = -10.0 \hat{y}$ with initial velocity $\vec{v}_0 = \hat{x} + \hat{y}$.

```fortran
real(8) :: k1, k2
common / couplings / k1, k2
f4=-k1 !dx4/dt=dv2/dt=a2
end function f4
!
real(8) function energy(t,x1,x2,v1,v2)
implicit none
real(8) :: t,x1,x2,v1,v2
real(8) :: k1,k2
common / couplings / k1,k2
energy = 0.5D0*(v1*v1+v2*v2) + k1*x2
end function energy
```

In order to calculate a projectile’s trajectory you may use the following commands:

```
> gfortran -02 rk2.f90 rk2_g.f90 -o rk2
> ./rk2
Runge–Kutta Method for 4–ODEs Integration
Enter coupling constants:
10.0 0.0
k1= 10.000000  k2= 0.000000
```
Figure 5.2: (Left) The parabolic trajectory of a projectile fired in a constant gravitational field $\vec{g} = -10.0 \hat{y}$ with initial velocity $\vec{v}_0 = \hat{x} + \hat{y}$. (Right) The deviation of the projectile’s energy from its initial value is due to numerical errors.

The analysis of the results contained in the file rk2.dat can be done using gnuplot:

```gnuplot
set terminal x11 1
plot "rk2.dat" using 1:2 with lines title "x(t)"
set terminal x11 2
plot "rk2.dat" using 1:3 with lines title "y(t)"
set terminal x11 3
plot "rk2.dat" using 1:4 with lines title "vx(t)"
set terminal x11 4
plot "rk2.dat" using 1:5 with lines title "vy(t)"
set terminal x11 5
plot "rk2.dat" using 1:($6-1.0)$ with lines title "E(t)-E(0)"
set terminal x11 6
set size square
set title "Trajectory"
plot "rk2.dat" using 2:3 with lines notit
```

The results can be seen in figures 5.1 and 5.2. We note a small increase in the mechanical energy which is due to the accumulation of numerical errors.

We can animate the trajectory by writing a script of gnuplot commands in a file rk2_animate.gpl
Before calling the script, the user must set the values of the variables icount, skip and nlines. Each time Gnuplot reads the script, it plots icount number of lines from rk2.dat. Then the script is read again and a new plot is made with skip lines more than the previous one, unless icount < nlines. The plotted “file” "<cat -n rk2.dat" is the standard output (stdout) of the command cat -n rk2.dat which prints to the stdout the contents of the file rk2.dat line by line, together with the line number. Therefore the plot command reads data which are the line number, the time, the coordinate $x$, the coordinate $y$ etc. The keyword using in

$$\text{using 3:($1<= \text{icount} ? \text{$4: 1/0$})}$$

instructs the plot command to use the 3rd column on the horizontal axis and if the first column is less than icount ($\text{$1<= icount}$) put on the vertical axis the value of the 4th column if the first column is less than icount. Otherwise ($\text{$1 > icount$}$) it prints an undefined number ($1/0$) which makes Gnuplot print nothing at all. You may also uncomment the command pause if you want to make the animation slower. In order to run the script from Gnuplot, issue the commands

```
$ gnuplot
> icount = 10
$ gnuplot
> skip = 200
$ gnuplot
> nlines = 20000
$ gnuplot
> load "rk2_animate.gpl"
```

The scripts shown above can be found in the accompanying software. More scripts can be found there that automate many of the boring procedures. The usage of two of these is explained below. The first one is in the file rk2_animate.csh:

```
> ./rk2_animate.csh -h
Usage: rk2_animate.csh -t [sleep time] -d [skip points] <file>
Default file is rk2.dat
Other options:
   -x: set lower value in xrange
```
The last line is a command that animates a trajectory read from the file \texttt{rk2.dat}. Each animation frame contains 500 more points than the previous one. The option \texttt{-r} calculates the plot range automatically. The option \texttt{-h} prints a short help message.

A more useful script is in the file \texttt{rk2.csh}.

```csh
> ./rk2.csh -h
Usage: rk2.csh -f <force> k1 k2 x10 x20 v10 v20 STEPS t0 tf
Other Options:
   -n Do not animate trajectory
Available forces (value of \texttt{<force>}):
1: ax=\-k1 ay=\-k2 y Harmonic oscillator
2: ax= 0 ay=\-k1 Free fall
3: ax=\-k2 vx ay=\-k2 vy y \- k1 Free fall + \
   air resistance \~ v
4: ax=\-k2 \|v\| vx ay=\-k2 \|v\|vy y \- k1 Free fall + \
   air resistance \~ v^2
5: ax= k1*x1/r^3 ay= k1*x2/r^3 Coulomb Force
....
```

The option \texttt{-h} prints operating instructions. A menu of forces is available, and a choice can be made using the option \texttt{-f}. The rest of the command line consists of the parameters read by the program in \texttt{rk2.f90}, i.e. the coupling constants \(k_1\), \(k_2\), the initial conditions \(x_{10}, x_{20}, v_{10}, v_{20}\) and the integration parameters \texttt{STEPS}, \texttt{t0} and \texttt{tf}. For example, the commands

```csh
> rk2.csh -f 2 -- 10.0 0.0 0.0 0.0 1.0 1.0 20000 0.0 0.2
> rk2.csh -f 1 -- 16.0 1.0 0.0 1.0 1.0 0.0 20000 0.0 6.29
> rk2.csh -f 5 -- 10.0 0.0 -10 0.2 10. 0.0 20000 0.0 3.00
```

compute the trajectory of a particle in the constant gravitational field discussed above, the trajectory of an anisotropic harmonic oscillator (\(k_1 = a_x = -\omega_1^2 x, k_2 = a_y = -\omega_2^2 y\)) and the scattering of a particle in a Coulomb field – try them! I hope that you will have enough curiosity to look “under the hood” of the scripts and try to modify them or create new ones. Some advise to the lazy guys: If you need to program your own force field follow the recipe: Write the code of your acceleration field
in a file named e.g. `rk2_myforce.f90` as we did with `rk2_g.f90`. Edit the file `rk2.csh` and modify the line

```bash
set forcecode = (hoc g vg v2g cb)
```
to

```bash
set forcecode = (hoc g vg v2g cb myforce)
```
(the variable `$forcecode` may have more entries than the ones shown above). Count the order of the string `myforce`, which is 6 in our case. In order to access this force field from the command line, use the option `-f 6:

```bash
> rk2.csh -f 6 .......
```

Now, we will study the effect of the air resistance on the motion of the projectile. For small velocities this is a force proportional to the velocity \( \vec{F}_r = -mk\vec{v} \), therefore

\[
\begin{align*}
a_x &= -kv_x \\
a_y &= -kv_y - g.
\end{align*}
\] (5.4)

By taking

\[
\begin{align*}
x(t) &= x_0 + \frac{v_{0x}}{k} \left( 1 - e^{-kt} \right) \\
y(t) &= y_0 + \frac{1}{k} \left( v_{0y} + \frac{g}{k} \right) \left( 1 - e^{-kt} \right) - \frac{g}{k} t \\
v_x(t) &= v_{0x} e^{-kt} \\
v_y(t) &= \left( v_{0y} + \frac{g}{k} \right) e^{-kt} - \frac{g}{k},
\end{align*}
\] (5.5)

we obtain the motion of a particle with terminal velocity \( v_y(+\infty) = -g/k \)

\( x(+\infty) = \text{const.}, y(+\infty) \sim t \).

The acceleration caused by the air resistance is programmed in the file `rk2_vg.f90`:

```bash
!========================================================
!The acceleration functions f3.f4(t,x1,x2,v1,v2) provided
!by the user
!========================================================
```
Free fall in constant gravitational field with
\[ ax = -k_2 \, v_x \quad \text{and} \quad ay = -k_2 \, v_y - k_1 \]

```fortran
real(8) function f3(t, x1, x2, v1, v2)
imPLICIT none
  real(8) :: t, x1, x2, v1, v2
  real(8) :: k1, k2
  common /couplings/k1, k2
f3 = -k2 * v1  !dx3/dt=dv1/dt=a1
end function f3
```

```fortran
real(8) function f4(t, x1, x2, v1, v2)
imPLICIT none
  real(8) :: t, x1, x2, v1, v2
  real(8) :: k1, k2
  common /couplings/k1, k2
f4 = -k2 * v2 - k1  !dx4/dt=dv2/dt=a2
end function f4
```

The results are shown in figure 5.3 where we see the effect of an increasing air resistance on the particle trajectory. The effect of a resistance force of the form \( \vec{F}_r = -k \vec{v} \) is shown in figure 5.4.

![Figure 5.3](image)

Figure 5.3: The trajectory of a projectile moving in a constant gravitational field \( \vec{g} = -10 \, \hat{y} \) with air resistance causing acceleration \( \vec{a}_r = -k \vec{v} \) for \( k = 0, 0.2, 1, 5, 10, 20, 30 \). The left plot has \( \vec{v}(0) = \hat{x} + \hat{y} \) and the right plot has \( \vec{v}(0) = 5\hat{x} + 5\hat{y} \).

### 5.3 Planetary Motion

Consider the simple planetary model of a “sun” of mass \( M \) and a planet “earth” at distance \( r \) from the sun and mass \( m \) such that \( m \ll M \). According to Newton’s law of gravity, the earth’s acceleration is

\[
\vec{a} = \vec{g} = -\frac{GM}{r^2} \vec{r} = -\frac{GM}{r^3} \vec{r},
\]  
(5.6)
5.3. **PLANETARY MOTION**

Figure 5.4: The trajectory of a projectile moving in a constant gravitational field \( \ddot{g} = -10 \hat{y} \) with air resistance causing acceleration \( \ddot{a}_r = -kv^2 \dot{v} \) for \( k = 0, 0.2, 1, 5, 10, 20, 30 \). The left plot has \( \ddot{v}(0) = \ddot{x} + \ddot{y} \) and the right plot has \( \ddot{v}(0) = 5\ddot{x} + 5\ddot{y} \).

where \( G = 6.67 \times 10^{-11} \frac{m^3}{kgr \cdot sec^2} \), \( M = 1.99 \times 10^{30} kgr, m = 5.99 \times 10^{24} kgr \).

When the hypothesis \( m \ll M \) is not valid, the two body problem is reduced to that of the one body problem with the mass replaced by the reduced mass \( \mu \)

\[
\frac{1}{\mu} = \frac{1}{m} + \frac{1}{M}.
\]

The force of gravity is a central force. This implies conservation of the angular momentum \( \vec{L} = \vec{r} \times \vec{p} \) with respect to the center of the force, which in turn implies that the motion is confined on one plane. We choose the \( z \) axis so that

\[
\vec{L} = L_z \hat{k} = m(xv_y - yv_x) \hat{k}.
\] (5.7)

The force of gravity is conservative and the mechanical energy

\[
E = \frac{1}{2} mv^2 - \frac{GmM}{r}
\] (5.8)

is conserved. If we choose the origin of the coordinate axes to be the center of the force, the equations of motion (5.6) become

\[
a_x = -\frac{GM}{r^3} x
\]

\[
a_y = -\frac{GM}{r^3} y,
\] (5.9)

where \( r^2 = x^2 + y^2 \). This is a system of two coupled differential equations for the functions \( x(t), y(t) \). The trajectories are conic sections which are either an ellipse (bound states - “planet”), a parabola (e.g. escape to
infinity when the particle starts moving with speed equal to the escape velocity) or a hyperbola (e.g. scattering).

Kepler’s third law of planetary motion states that the orbital period $T$ of a planet satisfies the equation

$$T^2 = \frac{4\pi^2}{GM}a^3,$$  \hspace{1cm} (5.10)

where $a$ is the semi-major axis of the elliptical trajectory. The eccentricity is a measure of the deviation of the trajectory from being circular

$$e = \sqrt{1 - \frac{b^2}{a^2}},$$  \hspace{1cm} (5.11)

where $b$ is the semi-minor axis. The eccentricity is 0 for the circle and tends to 1 as the ellipse becomes more and more elongated. The foci $F_1$ and $F_2$ are located at a distance $ea$ from the center of the ellipse. They have the property that for every point on the ellipse

$$PF_1 + PF_2 = 2a.$$  \hspace{1cm} (5.12)

The acceleration given to the particle by Newton’s force of gravity is programmed in the file rk2_cb.f90:

```
!=========================================================================

```
5.3. PLANETARY MOTION

We set \( k1 = -GM \) and take special care to avoid hitting the center of the force, the singular point at \((0, 0)\). The same code can be used for the electrostatic Coulomb field with \( k1 = qQ/4\pi\epsilon_0 \).

At first we study trajectories which are bounded. We set \( GM = 10 \), \( x(0) = 1.0, y(0) = 0, v_0x = 0 \) and vary \( v_0y \). We measure the period \( T \) and the length of the semi axes of the resulting ellipse. The results can be found in table 5.1. Some of the trajectories are shown in figure 5.5. There we can see the dependence of the size of the ellipse on the period. Figure 5.6 confirms Kepler’s third law of planetary motion given by equation (5.10).

In order to confirm Kepler’s third law of planetary motion numerically, we take the logarithm of both sides of equation (5.10)

\[
\ln T = \frac{3}{2} \ln a + \frac{1}{2} \ln \left( \frac{4\pi^2}{GM} \right). 
\]

Therefore, the points \((\ln a, \ln T)\) lie on a straight line. Using a linear least squares fit we calculate the slope and the intercept which should be equal to \( \frac{3}{2} \) and \( \frac{1}{2} \ln (4\pi^2/GM) \) respectively. This is left as an exercise.
Table 5.1: The results for the period $T$ and the length of the semi-major axis $a$ of the trajectory of planetary motion for $GM = 10$, $x(0) = 1.0$, $y(0) = 0$, $v_{0y} = 0$.

In the case where the initial velocity of the particle becomes larger than the escape velocity $v_e$, the particle escapes from the influence of the gravitational field to infinity. The escape velocity corresponds to zero mechanical energy, which gives

$$v_e^2 = \frac{2GM}{r}.$$  \hspace{1cm} (5.14)

When $GM = 10$, $x(0) = 1.0$, $y(0) = 0$, we obtain $v_e \approx 4.4721 \ldots$. The numerical calculation of $v_e$ is left as an exercise.

5.4 Scattering

In this section we consider scattering of particles from a central potential.\footnote{We refer the reader to [38], chapter 4.} We assume particles that follow unbounded trajectories that start from infinity and move almost free from the influence of the force field towards its center. When they approach the region of interaction they get deflected and get off to infinity in a new direction. We say that the particles have been scattered and that the angle between their original and final direction is the scattering angle $\theta$. Scattering problems are interesting because we can infer to the properties of the scattering potential from the distribution of the scattering angle. This approach is heavily used in today’s particle
accelerators for the study of fundamental interactions between elementary particles.

First we will discuss scattering of small hard spheres of radius \( r_1 \) by other hard spheres or radius \( R_2 \). The interaction potential\(^2\) is given by

\[
V(r) = \begin{cases} 
0 & r > R_2 + r_1 \\
\infty & r < R_2 + r_1 
\end{cases}, \tag{5.15}
\]

where \( r \) is the distance between the center of \( r_1 \) from the center of \( R_2 \). Assume that the particles in the beam do not interact with each other and that there is only one collision per scattering. Let \( J \) be the intensity of the beam\(^3\) and \( A \) its cross sectional area. Assume that the target has \( n \) particles per unit area. The cross sectional area of the interaction is \( \sigma = \pi (r_1 + R_2)^2 \) where \( r_1 \) and \( R_2 \) are the radii of the scattered particles and targets respectively (see figure (5.8)): All the spheres of the beam which lie outside this area are not scattered by the particular target. The

\(^2\)The so called hard core potential.

\(^3\)The number of particles crossing a surface perpendicular to the beam per unit time and unit area.

Figure 5.5: Planetary trajectories for \( GM = 10, x(0) = 1.0, y(0) = 0, v_{0x} = 0 \) and \( v_{0y} = 3.6, 3.8, 4.0, 4.1, 4.3 \). The numbers are the corresponding half periods.
Figure 5.6: Kepler’s third law of planetary motion for $GM = 10$. The points are the measurements taken from table 5.1. The solid line is the known analytic solution (5.10).

The total interaction cross section is

$$\Sigma = nA\sigma, \quad (5.16)$$

where $nA$ is the total number of target spheres which lie within the beam. On the average, the scattering rate is

$$N = J\Sigma = JnA\sigma. \quad (5.17)$$

The above equation is the definition of the total scattering cross section $\sigma$ of the interaction. The differential cross section $\sigma(\theta)$ is defined by the relation

$$dN = JnA\sigma(\theta) \, d\Omega, \quad (5.18)$$

where $dN$ is the number of particles per unit time scattered within the solid angle $d\Omega$. The total cross section is

$$\sigma_{\text{tot}} = \int_{\Omega} \sigma(\theta) \, d\Omega = \int \sigma(\theta) \sin \theta \, d\theta \, d\phi = 2\pi \int \sigma(\theta) \sin \theta \, d\theta. \quad (5.19)$$
In the last relation we used the cylindrical symmetry of the interaction with respect to the axis of the collision. Therefore

$$\sigma(\theta) = \frac{1}{nA J} \frac{dN}{2\pi \sin \theta \, d\theta}. \quad (5.20)$$

This relation can be used in experiments for the measurement of the differential cross section by measuring the rate of detection of particles within the space contained in between two cones defined by the angles $\theta$ and $\theta + d\theta$. This is the relation that we will use in the numerical calculation of $\sigma(\theta)$.

Generally, in order to calculate the differential cross section we shoot a particle at a target as shown in figure 5.9. The scattering angle $\theta$ depends on the impact parameter $b$. The part of the beam crossing the ring of radius $b(\theta)$, thickness $db$ and area $2\pi b \, db$ is scattered in angles between $\theta$ and $\theta + d\theta$. Since there is only one particle at the target we have that $nA = 1$. The number of particles per unit time crossing the ring is $J2\pi b \, db$, therefore

$$2\pi b(\theta) \, db = -2\pi \sigma(\theta) \sin \theta \, d\theta \quad (5.21)$$
5.4.1 Rutherford Scattering

The scattering of a charged particle with charge $q$ ("electron") in a Coulomb potential of a much heavier charge $Q$ ("nucleus") is called Rutherford scattering. In this case, the interaction potential is given by

$$V(r) = \frac{1}{4\pi\varepsilon_0} \frac{Q}{r}, \quad (5.22)$$

which accelerates the particle with acceleration

$$\ddot{a} = \frac{qQ}{4\pi\varepsilon_0 m} \frac{\hat{r}}{r^2} = \frac{\alpha}{r^3}. \quad (5.23)$$

The energy of the particle is $E = \frac{1}{2}mv^2$ and the magnitude of its angular momentum is $l = mv\hat{r}$, where $v = |\vec{v}|$. The dependence of the impact parameter on the scattering angle is

$$b(\theta) = \frac{\alpha}{v^2} \cot \frac{\theta}{2}. \quad (5.24)$$

Figure 5.8: Scattering of hard spheres. The scattering angle is $\theta$. The cross sectional area $\sigma$ is shown to the right.
5.4. SCATTERING

Figure 5.9: Beam particles passing through the ring $2\pi b \, db$ are scattered within the solid angle $d\Omega = 2\pi \sin \theta \, d\theta$.

Using equation (5.24) we obtain

$$\sigma(\theta) = \frac{\alpha^2}{4} \frac{1}{v^4} \sin^{-4} \frac{\theta}{2}. \quad (5.25)$$

Consider the scattering trajectories. The results for same charges are shown in figure 5.10. A similar figure is obtained in the case of opposite charges. In the latter case we have to take special care for small impact parameters $b < 0.2$ where the scattering angle is $\approx 1$. A large number of integration steps is needed in order to obtain the desired accuracy. A useful monitor of the accuracy of the calculation is the measurement of the energy of the particle which should be conserved. The results are shown in table 5.2. We will now describe a method for calculating the cross section by using equation (5.20). Alternatively we could have used equation (5.21) and perform a numerical calculation of the derivatives. This is left as an exercise for the reader. Our calculation is more like an experiment. We place a “detector” that “detects” particles scattered within angles $\theta$ and $\theta + \delta\theta$. For this reason we split the interval $[0, \pi]$ in $N_b$ bins so that $\delta\theta = \pi/N_b$. We perform “scattering experiments” by varying $b \in [b_m, b_M]$ with step $\delta b$. Due to the symmetry of the problem we fix $\phi$ to be a constant, therefore a given $\theta$ corresponds to a cone with an opening angle $\theta$ and an apex at the center of scattering. For given $b$ we measure the scattering angle $\theta$ and record the number of particles per unit time $\delta N \propto b \delta b$. The latter is proportional to the area of the ring of radius $b$. All we need now is the beam intensity $J$ which is the total number of particles per unit time $J \propto \sum_i b \delta b$ (note than in the ratio $\delta N/J$ the
Figure 5.10: Rutherford scattering trajectories. We set $k_1 \equiv \frac{q Q}{\varepsilon_0 m} = 1$ (see code in the file rk2_cb.f90) and $b = 0.08, 0.015, 0.020, 0.035, 0.080, 0.120, 0.200, 0.240, 0.320, 0.450, 0.600, 1.500$. The initial position of the particle is at $x(0) = -50$ and its initial velocity is $v = 3$ in the $x$ direction. The number of integration steps is 1000, the initial time is 0 and the final time is 30.

The proportionality constant and $\delta b$ cancel) and the solid angle $2\pi \sin(\theta) \delta \theta$. Finally we can easily use equation (5.19) in order to calculate the total cross section $\sigma_{\text{tot}}$. The program that performs this calculation is in the file scatter.f90 and it is a simple modification of the program in rk2.f90:

```fortran

                        angle,angle*rad2deg,sigma
    sigmatot = sigmatot + sigma*dOmega
  enddo
  write(11,*) 'sigmatot=', sigmatot
Figure 5.12: Differential cross section of the Rutherford scattering like in figure 5.11. The solid line is the function $1/(4 \times 3^4)x$ from which we can deduce the functional form of $\sigma(\theta)$.

```fortran
close(11)
end program scatter_cross_section
```

The results are recorded in the file scatter.dat. An example session that reproduces figures 5.11 and 5.12 is

```bash
> gfortran scatter.f90 rk2_cb.f90 -o scatter
> ./scatter
Runge–Kutta Method for 4–ODEs Integration
Enter coupling constants:
1.0  0.0
k1=  1.00000  k2=  0.00000
Enter Nt,Ti,Tf,X10,X20,V10,V20:
5000  0  30  -50  0.02  3  0
Enter final impact parameter X20F and step dX20:
1  0.0002
Nt=  5000
Time: Initial T0 =  0.00000  Final TF=  30.00000
X1(T0)= -50.00000  X2(T0)=  2.00000E-002
V1(T0)=  3.00000  V2(T0)=  0.00000
Impact par X20F =  1.00000  dX20 =  2.00000E-004
```
The results can be plotted with the gnuplot commands:

```
set log
plot [:1000] "<grep ds= scatter.dat" \
  u ((sin($2/2))**(-4))($4) notit, \
  (1./(4.*3.*4))^x notit
unset log
set log y
plot [:] "<grep ds= scatter.dat" u 2:4 notit, \
  (1./(4.*3.*4))*(sin(x/2))**(-4) notit
```

The results are in a very good agreement with the theoretical ones given by (5.25). The next step will be to study other central potentials whose solution is not known analytically.

### 5.4.2 More Scattering Potentials

Consider scattering from a force field

\[ \vec{F} = f(r) \hat{\mathbf{r}}, \quad f(r) = \begin{cases} \frac{1}{r^2} - \frac{r}{a^3} & r \leq a \\ 0 & r > a \end{cases} . \tag{5.26} \]

This is a very simple classical model of the scattering of a positron $e^+$ by the hydrogen atom. The positron has positive charge $+e$ and the hydrogen atom consists of a positively charged proton with charge $+e$ in an electron cloud of opposite charge $-e$. We set the scales so that $m_{e^+} = 1$ and $e^2/4\pi\epsilon_0 = 1$. We will perform a numerical calculation of $b(\theta)$, $\sigma(\theta)$ and $\sigma_{\text{tot}}$.

The potential energy is given by

\[ f(r) = -\frac{dV(r)}{dr} \Rightarrow V(r) = \frac{1}{r} + \frac{r^2}{2a^2} - \frac{3}{2a^2} . \tag{5.27} \]

where $V(r) = 0$ for $r \geq a$. The program containing the calculation of the acceleration caused by this force can be found in the file `rk_hy.f90`:

```

0.0D0 
\end{cases} \]

\[ \text{endif} \]

\[ \text{energy} = 0.5D0*(v1*v1+v2*v2) + Vr \]

The results are shown in figures 5.13–5.14. We find that \( \sigma_{\text{tot}} = \pi a^2 \) (see problem 5.10).

Figure 5.13: The impact parameter \( b(\theta) \) for the potential given by equation (5.27) for different values of the initial velocity \( v \). We set \( a = 1 \), \( x(0) = -5 \) and made 4000 integration steps from \( t_i = 0 \) to \( t_f = 40 \).

Another interesting dynamical field is given by the Yukawa potential. This is a phenomenological model of nuclear interactions:

\[ V(r) = k \frac{e^{-r/a}}{r} . \] (5.28)

This field can also be used as a model of the effective interaction of electrons in metals (Thomas–Fermi) or as the Debye potential in a classic plasma. The resulting force is

\[ \vec{F}(r) = f(r) \hat{r} , \quad f(r) = k \frac{e^{-r/a}}{r^2} \left( 1 + \frac{r}{a} \right) . \] (5.29)
Figure 5.14: The function $\sigma(\theta)$ for the potential given by equation (5.27) for different values of the initial velocity $v$. We set $a = 1$, $x(0) = -5$ and the integration is performed by making 4000 steps from $t_i = 0$ to $t_f = 40$.

The program of the resulting acceleration can be found in the file rk2_yu.f90. The results are shown in figures 5.15–5.16.

### 5.5 More Particles

In this section we will generalize the discussion of the previous paragraphs in the case of a dynamical system with more degrees of freedom. The number of dynamical equations that need to be solved depends on the number of degrees of freedom and we have to write a program that implements the 4th order Runge–Kutta method for an arbitrary number of equations $\text{NEQ}$. We will explain how to allocate memory dynamically, in which case the necessary memory storage space, which depends on $\text{NEQ}$, is allocated at the time of running the program and not at compilation time.

Until now, memory has been allocated statically. This means that arrays have sizes which are known at compile time. For example, in the program rk2.f90 the integer parameter $P$ had a given value which determined the size of all arrays using the declarations:
5.5. MORE PARTICLES

Figure 5.15: The function $b(\theta)$ for the Yukawa scattering for several values of the initial velocity $v$. We set $a = 1$, $k = 1$, $x(0) = -50$ and the integration is performed with 5000 steps from $t_i = 0$ to $t_f = 30$. The lines marked as cb are equation (5.24) of the Rutherford scattering.

Changing $P$ after compilation is impossible and if this becomes necessary we have to edit the file, change the value of $P$ and recompile. Dynamical memory allocation allows us to read in $Nt$ and $NEQ$ at execution time and then ask from the operating system to allocate the necessary memory. All we have to do is to declare the shape of the arrays (i.e. how many indices they take) and give them the allocatable attribute. The needed memory can be asked for at execution time by calling the function ALLOCATE. Here is an example:

```fortran
integer, parameter :: P=1010000
real(8), dimension(P) :: T,X1,X2,V1,V2

integer Nt,NEQ
real(8), allocatable :: T (:), X (:,:), X0(:) ! Rank-1 array
real(8), allocatable :: T (:), X (:,:), X0(:) ! Rank-2 array
real(8), allocatable :: T (:), X (:,:), X0(:) ! Rank-1 array

read *,Nt
```
Figure 5.16: The function $b(\theta)$ for the Yukawa scattering for several values of the range $a$ of the force. We set $v = 4.0$, $k = 1$, $x(0) = -50$ and the integration is performed with 5000 steps from $t_i = 0$ to $t_f = 30$.

```fortran
! call finit(NEQ)
allocate(X0(NEQ))
allocate(T(Nt))
allocate(X(Nt,NEQ))
...
! (compute with X0,T,X)
...
deallocate(X0)
deallocate(X)
deallocate(T)
(X0,T,X are not usable anymore)
...

 subroutine finit(NEQ)
    NEQ = 4
 end subroutine finit
```

In this program the arrays have the allocatable attribute and for each : they have an extra index. Therefore the arrays $T,X0$ are rank-1 arrays and have only one index, whereas the array $X$ is a rank-2 array and has two indices. The user enters the value of $N_t$ and the subroutine `finit`
sets the value of NEQ. The calls to the function ALLOCATE allocate the necessary memory. If memory allocation is successful, then the arrays can be used in the same way as the statically allocated ones. When allocatable arrays are not necessary anymore we should make a call to the function DEALLOCATE which returns the unused memory back to the system. Otherwise our program might suffer from “memory leaks” if e.g. the memory is repeatedly asked in a loop that calls a function that allocates memory without deallocating it in the end. Dynamical memory allocation is very convenient but for high performance computing static allocation might be preferable so that the compiler performs a more efficient optimization.

The main program will be written in the file rkA.f90, whereas the force-dependent part of the code will be written in files with names of the form rkA_XXX.f90. In the latter, the user must program a subroutine \( f(t, X, \text{dXdt}) \) which takes as input the time \( t \) and the values of the functions \( X(\text{NEQ}) \) and outputs the values of their derivatives \( \text{dXdt}(\text{NEQ}) \) at time \( t \). The function \( \text{finit}(\text{NEQ}) \) sets the number of functions in \( f \) and it is called once during the initialization phase of the program.

The program in the file \( \text{rkA.f90} \) is listed below:

```fortran
Program to solve an ODE system using the 4th order Runge–Kutta Method
NEQ: Number of equations
User supplies two subroutines:
\( f(t, x, xdot) \) : with real(8) :: t, x(NEQ), xdot(NEQ) which
given the time \( t \) and current values of functions \( x(\text{NEQ}) \)
returns the values of derivatives: \( xdot = dx/dt \)
The values of two coupling constants \( k1, k2 \) may be used
in \( f \) which are read in the main program and stored in
common /couplings/k1, k2
\( \text{finit}(\text{NEQ}) \) : sets the value of \( \text{NEQ} \)

User Interface:
\( k1, k2 \) : real(8) coupling constants
\( Nt, Ti, Tf \) : \( Nt-1 \) integration steps, initial/final time
\( X0 \) : real(8), dimension(NEQ) : initial conditions

Output:
```

\(^4\)We assume that \( Nt, \text{NEQ} \) are positive and small enough so that the requested memory is available. It is better to use the call allocate(T(Nt), STAT=IERR). The non zero value of IERR after the call indicates a successful allocation and the following test stops the program otherwise: IF(IERR .eq. 0) STOP 'Memory allocation for T failed'

\(^5\)In the accompanying software you will find the files rkN.f90 and rkN_XXX.f90 which show you how to write the same program using static memory allocation.

subroutine RKSTEP(t,x,dt)

! Runge-Kutta Integration routine
!========================================================

implicit none
integer :: NEQ
real(8), dimension(NEQ) :: x
real(8) :: t, dt, tt
real(8), dimension(NEQ) :: k1,k2,k3,k4,xx
real(8) :: h, h2, h6

! We need explicit interface, since f has assumed-shape!
arrays as arguments.

INTERFACE
    subroutine f(t_inrif,x_inrif,xdot_inrif)
        implicit none
        real(8) :: t_inrif
        real(8), dimension(:) :: x_inrif, xdot_inrif
    end subroutine f
END INTERFACE

h =dt ! h =dt, integration step
h2=0.5D0*h ! h2= h/2
h6=h/6.0D0 ! h6= h/6

! We need explicit interface, since f has assumed-shape!
arrays as arguments.

CALL f(t, x, k1); xx = x + h2*k1; tt = t+h
CALL f(tt, xx, k2); xx = x + h2*k2; tt = t+h
CALL f(tt, xx, k3); xx = x + h*k3; tt = t+h
CHAPTER 5. PLANAR MOTION

```fortran
  call f(tt, xx, k4)
  t = t + h
  x = x + h * (k1 + 2.0D0 * (k2 + k3) + k4)
end subroutine RKSTEP
```

Note the use of array sections:

```fortran
write(11, '(2000G28.16)') T(i), X(i,:)
X(1,:) = X0
X(i,:) = Xs
```

The expression `X(1,:)` refers to the first row of the array `X`. The arrays `X0` and `X(1,:)` are conformable and we can assign the entries in `X(1,:)` equal to the entries in `X0`, i.e. `X(1,1) = X0(1), X(1,2) = X0(2), ... , X(1,NEQ) = X0(NEQ) in only one statement `X(1,:) = X0`. Similarly, the statement `write(...) X(i,:)` prints the whole `i`-th row of the array `X` whereas the statement `X(i,:) = Xs` assigns `X(i,1) = Xs(1), X(i,2) = Xs(2), ... , X(i,NEQ) = Xs(NEQ)`. Note the vector operations:

```fortran
xx = x + h * k1
x = x + h * (k1 + 2.0D0 * (k2 + k3) + k4)
```

which are equivalent to the following do loops

```fortran
do i = 1, NEQ
   xx(i) = x(i) + h * k1(i)
endo
do i = 1, NEQ
   x(i) = x(i) + h * (k1(i) + 2.0D0 * (k2(i) + k3(i)) + k4(i))
endo
```

A few words in order to explain what is an INTERFACE block. Up to now we declared only the type of the functions in the calling program. When the arguments of the function are arrays for which we only know their shape and not their size (assumed-shape arrays), the compiler needs more information. We need to declare the arguments, their types and, in case they are arrays, their shapes as well. Each program that calls these functions should include an INTERFACE block which provides this information. For the functions `f` and `energy`, the corresponding INTERFACE block is

```fortran
INTERFACE
```
You may create files like e.g. interfaces.inc with groups of INTERFACE blocks and include them in all subprograms that use them with the statement include "interfaces.inc".

Consider three particles of equal mass exerting a force of gravitational attraction on each other like the ones shown in figure 5.17. The forces

\[ F_{ij} = \frac{G m_i m_j}{r_{ij}^2} \]

The same program can be used for three equal charges exerting an electrostatic force on each other, which can be either attractive or repulsive.
CHAPTER 5. PLANAR MOTION

exerting on each other are given by

\[ \vec{F}_{ij} = \frac{mk_1}{r_{ij}^3} \vec{r}_{ij}, \quad i, j = 1, 2, 3, \tag{5.30} \]

where \( k_1 = -Gm \) and the equations of motion become \((i = 1, 2, 3)\)

\[ \begin{align*}
\frac{dx_i}{dt} &= v_{ix} \\
\frac{dv_{ix}}{dt} &= k_1 \sum_{j=1, j \neq i}^{3} \frac{x_i - x_j}{r_{ij}^3} \\
\frac{dy_i}{dt} &= v_{iy} \\
\frac{dv_{iy}}{dt} &= k_1 \sum_{j=1, j \neq i}^{3} \frac{y_i - y_j}{r_{ij}^3}, \tag{5.31}
\end{align*} \]

where \( r_{ij}^2 = (x_i - x_j)^2 + (y_i - y_j)^2 \). The total energy of the system is

\[ E/m = \frac{1}{2}(v_1^2 + v_2^2) + \sum_{i,j=1, j<i}^{3} \frac{k_1}{r_{ij}}. \tag{5.32} \]

The relations shown above are programmed in the file `rkA_3pcb.f90` listed below:

```fortran
!==================================================================
!Sets number of equations
!==================================================================

```
In order to run the program and see the results look at the commands in the shell script in the file rK\textsc{A}_3\textsc{pcb}.csh. In order to run the script use
command

> rkA_3pcb.csh -0.5 4000 1.5 -1 0.1 1 0 1 -0.1 -1 0 0.05 1 0 -1

which will run the program setting $k_1 = -0.5$, $\vec{r}_1(0) = -\hat{x} + 0.1\hat{y}$, $\vec{v}_1(0) = \hat{x}$, $\vec{r}_2(0) = \hat{x} - 0.1\hat{y}$, $\vec{v}_2(0) = -\hat{x}$, $\vec{r}_3(0) = 0.05\hat{x} + \hat{y}$, $\vec{v}_3(0) = -\hat{y}$, $Nt = 4000$ and $t_f = 1.5$. 
5.6 Problems

5.1 Reproduce the results shown in figures 5.3 and 5.4. Compare your results to the known analytic solution.

5.2 Write a program for the force on a charged particle in a constant magnetic field \( \vec{B} = B \hat{k} \) and compute its trajectory for \( \vec{v}(0) = v_{0x}\hat{x} + v_{0y}\hat{y} \). Set \( x(0) = 1, y(0) = 0, v_{0y} = 0 \) and calculate the resulting radius of the trajectory. Plot the relation between the radius and \( v_{0x} \). Compare your results to the known analytic solution. (assume non relativistic motion)

5.3 Consider the anisotropic harmonic oscillator \( a_x = -\omega_1^2 x, a_y = -\omega_2^2 y \). Construct the Lissajous curves by setting \( x(0) = 0, y(0) = 1, v_x(0) = 1, v_y(0) = 0, t_f = 2\pi, \omega_2^2 = 1, \omega_1^2 = 1, 2, 4, 9, 16, \ldots \). What happens when \( \omega_1^2 \neq n\omega_2^2 \)?

5.4 Reproduce the results displayed in table 5.1 and figures 5.5 and 5.6. Plot \( \ln a \) vs \( \ln T \) and calculate the slope of the resulting straight line by using the linear least squares method. Is it what you expect? Calculate the intercept and compare your result with the expected one.

5.5 Calculate the angular momentum with respect to the center of the force at each integration step of the planetary motion and check whether it is conserved. Show analytically that conservation of angular momentum implies that the position vector sweeps areas at constant rate.

5.6 Calculate the escape velocity of a planet \( v_e \) for \( GM = 10.0 \), \( y(0) = 0.0 \), \( x_0 = x(0) = 1 \) using the following steps: First show that \( v_0^2 = -GM(1/a) + v_e^2 \). Then set \( v_x(0) = 0, v_y(0) = v_0 \). Vary \( v_y(0) = v_0 \) and measure the resulting semi-major axis \( a \). Determine the intercept of the resulting straight line in order to calculate \( v_e \).

5.7 Repeat the previous problem for \( x_0 = 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0 \). From the \( v_e = f(1/x_0) \) plot confirm the relation (5.14).

5.8 Check that for the bound trajectory of a planet with \( GM = 10.0 \), \( x(0) = 1, y(0) = 0.0, v_x(0) = 0, v_y(0) = 4 \) you obtain that \( F_1P + F_2P = 2a \) for each point \( P \) of the trajectory. The point \( F_1 \) is the center of the force. After determining the semi-major axis \( a \) numerically, the point \( F_2 \) will be taken symmetric to \( F_1 \) with respect to the center of the ellipse.
5.9 Consider the planetary motion studied in the previous problem. Apply a momentary push in the tangential direction after the planet has completed 1/4 of its elliptical orbit. How stable is the particle trajectory (i.e., what is the dependence of the trajectory on the magnitude and the duration of the push)? Repeat the problem when the push is in the vertical direction.

5.10 Consider the scattering potential of the positron-hydrogen system given by equation (5.26). Plot the functions $f(r)$ and $V(r)$ for different values of $a$. Calculate the total cross section $\sigma_{tot}$ numerically and show that it is equal to $\pi a^2$.

5.11 Consider the Morse potential of diatomic molecules:

$$V(r) = D (\exp(-2\alpha r) - 2 \exp(-\alpha r))$$

where $D, \alpha > 0$. Compute the solutions of the problem numerically in one dimension and compare them to the known analytic solutions when $E < 0$:

$$x(t) = \frac{1}{\alpha} \ln \left\{ \frac{D - \sqrt{D(D - |E|)} \sin(\alpha t \sqrt{2|E|/m + C})}{|E|} \right\}$$

where the integration constant as a function of the initial position and energy is given by

$$C = \sin^{-1} \left\{ \frac{D - |E| e^{\alpha x_0}}{\sqrt{D(D - |E|)}} \right\}.$$  

We obtain a periodic motion with an energy dependent period $= (\pi/\alpha) \sqrt{2m/|E|}$. For $E > 0$ we obtain

$$x(t) = \frac{1}{\alpha} \ln \left\{ \frac{\sqrt{D(D + E)} \cosh(\alpha t \sqrt{2E/m + C}) - D}{|E|} \right\}$$

whereas for $E = 0$

$$x(t) = \frac{1}{\alpha} \ln \left\{ \frac{1}{2} + \frac{D\alpha^2}{m}(t + C)^2 \right\}.$$  

In these equations, the integration constant $C$ is given by a different relation and not by equation (5.35). Compute the motion in phase space $(x, \dot{x})$ and study the transition from open to closed trajectories.
5.12 Consider the effective potential term \( V_{\text{eff}}(r) = \frac{l^2}{2mr^2} (l \equiv \vec{L}) \) in the previous problem. Plot the function \( V_{\text{tot}}(r) = V(r) + V_{\text{eff}}(r) \) for \( D = 20 \), \( \alpha = 1 \), \( m = 1 \), \( l = 1 \), and of course for \( r > 0 \). Determine the equilibrium position and the ionization energy.

Calculate the solutions \( x(t) \), \( y(t) \), \( y(x) \), \( r(t) \) on the plane for \( E > 0 \), \( E = 0 \), and \( E < 0 \) numerically. In the \( E < 0 \) case consider the scattering problem and calculate the functions \( b(\theta) \), \( \sigma(\theta) \) and the total cross section \( \sigma_{\text{tot}} \).

5.13 Consider the potential of the molecular model given by the force \( \vec{F}(r) = f(r) \hat{r} \) where \( f(r) = 24(2/r^{13} - 1/r^7) \). Calculate the potential \( V(r) \) and plot the function \( V_{\text{tot}}(r) = V(r) + V_{\text{eff}}(r) \). Determine the equilibrium position and the ionization energy.

Consider the problem of scattering and calculate \( b(\theta) \), \( \sigma(\theta) \) and \( \sigma_{\text{tot}} \) numerically. How much do your results depend on the minimum scattering angle?

5.14 Compute the trajectories of a particle under the influence of a force \( \vec{F} = -k/r^3 \hat{r} \). Determine appropriate initial conditions that give a spiral trajectory.

5.15 Compute the total cross section \( \sigma_{\text{tot}} \) for the Rutherford scattering both analytically and numerically. What happens to your numerical results as you vary the integration limits?

5.16 Write a program that computes the trajectory of a particle that moves on the plane in the static electric field of \( N \) static point charges.

5.17 Solve the three body problem described in the text in the case of three different electric charges by making the appropriate changes to the program in the file rkA_3cb.f90.

5.18 Two charged particles of equal mass and charge are moving on the \( xy \) plane in a constant magnetic field \( \vec{B} = B\hat{z} \). Solve the equations of motion using a 4th order Runge–Kutta Method. Plot the resulting trajectories for the initial conditions that you will choose.

5.19 Three particles of equal mass \( m \) are connected by identical springs. The springs’ spring constant is equal to \( k \) and their equilibrium length is equal to \( l \). The particles move without friction on a horizontal plane. Solve the equations of motion of the system numerically by using a 4th order Runge–Kutta Method. Plot the resulting
trajectories for the initial conditions that you will choose. (Hint: Look in the files rkA_3hoc.f90, rkA_3hoc.csh.)

Figure 5.18: Two identical particles are attached to thin weightless rods of length $l$ and they are connected by an ideal weightless spring with spring constant $k$ and equilibrium length $l$. The rods are hinged to the ceiling at points whose distance is $l$. (Problem 5.20).

5.20 Two identical particles are attached to thin weightless rods of length $l$ and they are connected by an ideal weightless spring with spring constant $k$ and equilibrium length $l$. The rods are hinged to the ceiling at points whose distance is $l$ (see figure 5.18). Compute the Lagrangian of the system and the equations of motion for the degrees of freedom $\theta_1$ and $\theta_2$. Solve these equations numerically by using a 4th order Runge–Kutta method. Plot the positions of the particles in a Cartesian coordinate system and the resulting trajectory. Study the normal modes for small angles $\theta_1 \lesssim 0.1$ and compute the deviation of the solutions from the small oscillation approximation as the angles become larger. (Hint: Look in the files rk_cpend.f90, rk_cpend.csh)

5.21 Repeat the previous problem when the hinges of the rods slide without friction on the $x$ axis.

5.22 Repeat problem 5.20 by adding a third pendulum to the right at distance $l$. 
Chapter 6

Motion in Space

In this chapter we will study the motion of a particle in space (three dimensions). We will also discuss the case of the relativistic motion, which is important if one wants to consider the motion of particles moving with speeds comparable to the speed of light. This will be an opportunity to use an *adaptive stepsize* Runge-Kutta method for the numerical solution of the equations of motion. We will use the open source code rksuite¹ available at the Netlib² repository. Netlib is an open source, high quality repository for numerical analysis software. The software it contains is used by many researchers in their high performance computing programs and it is a good investment of time to learn how to use it.

The technical skill that you will exercise in this chapter is looking for solutions to your numerical problems provided by software written by others. It is important to be able to locate the optimal solution to your problem, find the relevant functions, read the software’s documentation carefully and filter out the necessary information in order to call and link the functions to your program.

---

²www.netlib.org
6.1 Adaptive Stepsize Control for Runge–Kutta Methods

The three dimensional equation of motion of a particle is an initial value problem given by the equations (6.1)

\[
\begin{align*}
\frac{dx}{dt} &= v_x \\
\frac{dy}{dt} &= v_y \\
\frac{dz}{dt} &= v_z \\
\frac{dv_x}{dt} &= a_x(t, x, v_x, y, v_y, z, v_z) \\
\frac{dv_y}{dt} &= a_y(t, x, v_x, y, v_y, z, v_z) \\
\frac{dv_z}{dt} &= a_z(t, x, v_x, y, v_y, z, v_z).
\end{align*}
\]

(6.1)

For its numerical solution we will use an adaptive stepsize Runge–Kutta algorithm for increased performance and accuracy. Adaptive stepsize is used in cases where one needs to minimize computational effort for given accuracy goal. The method frequently changes the time step during the integration process, so that it is set to be large through smooth intervals and small when there are abrupt changes in the values of the functions. This is achieved by exercising error control either by monitoring a conserved quantity or by computing the same solution using two different methods. In our case, two Runge-Kutta methods are used, one of order \( p \) and one of order \( p + 1 \), and the difference of the results is used as an estimate of the truncation error. If the error needs to be reduced, the step size is reduced and if it is satisfactorily small the step size is increased. For the details we refer the reader to [31]. Our goal is not to analyze and understand the details of the algorithm, but to learn how to find and use appropriate and high quality code written by others. The link \texttt{http://www.netlib.org/ode/} reads

lib rksuite
alg Runge–Kutta
for initial value problem for first order ordinary differential
equations. A suite of codes for solving IVPs in ODEs. A choice
of RK methods is available. Includes an error assessment
facility and a sophisticated stiffness checker. Template programs
and example results provided. Supersedes RKF45, DDERKF,
D02PAF.
ref RKSUITE. Softreport 92–S1, Dept of Math. SMU. Dallas.

Texas
lang Fortran
6.1. ADAPTIVE STEPSIZE CONTROL FOR RUNGE–KUTTA METHODS

There, we learn that the package provides code for Runge–Kutta methods, whose source is open and written in the Fortran language. We also learn that the code is written for double precision variables, which is suitable for our problem. Last, but not least, we are also happy to learn that it is written by highly reputable people! We download the files rksuite.f, rksuite.doc, details.doc, templates, readme.

In order to link the subroutines provided by the suite to our program we need to read the documentation carefully. In the general case, documentation is available on the web (html, pdf,...), bundled files with names like README, INSTALL, in whole directories with names like doc/, online help in man or info pages and finally in good old fashioned printed manuals. Good quality software is also well documented inside the source code files, something that is true for the software at hand.

In order to link the suite’s subroutines to our program we need the following basic information:

- **INPUT DATA:** This is the necessary information that the program needs in order to perform the calculation. In our case, the minimal such information is the initial conditions, the integration time interval and the number of integration steps. The user should also provide the functions on the right hand side of (6.1). It might also be necessary to provide information about the desired accuracy goal, the scale of the problem, the hardware etc.

- **OUTPUT DATA:** This is the information on how we obtain the results of the calculation for further analysis. Information whether the calculation was successful and error free could also be provided.

- **WORKSPACE:** This is information on how we provide the necessary memory space used in the intermediate calculations. Such space needs to be provided by the user in programming languages where dynamical memory allocation is not possible, like in Fortran 77, and the size of workspace depends on the parameters of the calling program.

It is easy to install the software. All the necessary code is in one file rksuite.f. The file rksuite.doc contains the documentation. There we read that we need to inform the program about the hardware dependent

---

³This is a simple text file which you can read with the command less rksuite.doc or with emacs.
accuracy of floating point numbers. We need to set the values of three variables:

... RKSUITE requires three environmental constants OUTCH, MCHEPS, DWARF. When you use RKSUITE, you may need to know their values. You can obtain them by calling the subroutine ENVIRN in the suite:

    CALL ENVIRN(OUTCH,MCHEPS,DWARF)

returns values

OUTCH — INTEGER
    Standard output channel on the machine being used.

MCHEPS — DOUBLE PRECISION
    The unit of roundoff, that is, the largest positive number such that 1.0D0 + MCHEPS = 1.0D0.

DWARF — DOUBLE PRECISION
    The smallest positive number on the machine being used.

... ************ Installation Details ************

All machine–dependent aspects of the suite have been isolated in the subroutine ENVIRN in the rksuite.f file. Certain environmental parameters must be specified in this subroutine. The values in the distribution version are those appropriate to the IEEE arithmetic standard. They must be altered, if necessary, to values appropriate to the computing system you are using before calling the codes of the suite. If the IEEE arithmetic standard values are not appropriate for your system, appropriate values can often be obtained by calling routines named in the Comments of ENVIRN.

... The variables OUTCH, MCHEPS, DWARF are defined in the subroutine ENVIRN. They are given generic default values but the programmer is free to change them by editing ENVIRN. We should identify the routine in the file rksuite.f and read the comments in it:

    ... SUBROUTINE ENVIRN(OUTCH,MCHEPS,DWARF)
    ...

⁴These are lines that begin with a C as this is old fixed format Fortran code.
### 6.1. ADAPTIVE STEPSIZE CONTROL FOR RUNGE–KUTTA METHODS

The following six statements are to be Commented out after verification that the machine and installation dependent quantities are specified correctly.

```
C After verification that the machine and installation dependent quantities are specified correctly,
... WRITE(*,*) ' Before using RKSUITE, you must verify that the 
WRITE(*,*) machine- and installation-dependent quantities 
WRITE(*,*) specified in the subroutine ENVIRN are correct, 
WRITE(*,*) and then Comment these WRITE statements and the 
WRITE(*,*) STOP statement out of ENVIRN.
STOP 
... 
```

The following values are appropriate to IEEE arithmetic with the typical standard output channel.

```
OUTCH = 6
MCHEPS = 1.11D-16
DWARF = 2.23D-308
```

All we need to do is to comment out the WRITE and STOP commands since we will keep the default values of the OUTCH, MCHEPS, DWARF variables:

```
C The following values are appropriate to IEEE 
C arithmetic with the typical standard output channel.
C
OUTCH = 6
MCHEPS = 1.11D-16
DWARF = 2.23D-308
```

In order to check whether the default values are satisfactory, we can use the Fortran intrinsic functions EPSILON() and TINY(). In the file test_envirn.f90, we write a small test program

```
program testme
implicit none
integer :: OUTCH
real(8) :: DWARF, MCHEPS
real(8) :: x
OUTCH = 6 ! This is pretty much a standard
MCHEPS = epsilon(x)/2.0D0
DWARF = tiny(x)
write(6,101)OUTCH,MCHEPS,DWARF
101 format(I4,2E30.18)
end program testme
```

We compile and run the above program as follows:

```
> gfortran test_envirn.f90 -o test_envirn
```
We conclude that our choices are satisfactory.

Next we need to learn how to use the subroutines in the suite. By carefully reading rksuite.doc we learn the following: The interface to the adaptive stepsize Runge–Kutta algorithm is the routine UT (UT = “Usual Task”). The routine can use a 2nd-3rd (RK23) order Runge-Kutta pair for error control (METHOD=1), a 4th-5th (RK45) order pair (METHOD=2) or a 7th-8th (RK78) order pair (METHOD=3). We will set METHOD=2 (RK45).

The routine SETUP must be called before UT for initialization. The user should provide a function F that calculates the derivatives of the functions we integrate for, i.e. the right hand side of 6.1.

The fastest way to learn how to use the above routines is “by example”. The suite include a templates package which can be unpacked by executing the commands in the file templates using the sh shell:

```
> sh templates
tmpl1.out
tmpl1a.f
...
```

The file tmpl1a.f contains the solution of the simple harmonic oscillator and has many explanatory comments in it. We encourage the reader to study it carefully, run it and test its results.

After we become wise enough, we write the driver for the integration routine UT, which can be found in the file rk3.f90:

```
!========================================================================

do i=1,STEPS
   t = T0 + i*dt
   call UT(F,t,tstep,Y,YP,YMAX,WORK,UFLAG)
   if (UFLAG.GT.2) exit !exit the loop: go after enddo
   write(11,100) tstep,Y(1),Y(2),Y(3),Y(4),Y(5),Y(6),&
      energy(tstep,Y)
endo
close(11)
end program rk3_solve
All common parameters and variables are declared in an include file `rk3.inc`. This is necessary in order for them to be accessible by the function \( F \) which calculates the derivatives. The contents of this file are substituted in each line containing the command `include 'rk3.inc'`.

```plaintext
! Basic definitions of variables for the suite rksuite
implicit none
!NEQ is the number of equations, 6 in 3 dimensions
!METHOD=2 is for RK45.
INTEGER NEQ, LENWRK, METHOD
PARAMETER (NEQ=6, LENWRK=32*NEQ, METHOD=2)
REAL *8 k1, k2, k3, k4  ! force couplings
COMMON /COUPLINGS/k1, k2, k3, k4
```

The number of differential equations is set equal to \( \text{NEQ}=6 \). The integration method is set by the choice \( \text{METHOD}=2 \). The variable \( \text{LENWRK} \) sets the size of the workspace needed by the suite for the intermediate calculations.

The main program starts with the user interface. The initial state of the particle is stored in the array \( \text{YSTART} \) in the positions 1...6. The first three positions are the coordinates of the initial position and the last three the components of the initial velocity. Then we set some variables that determine the behavior of the integration program (see the file `rksuite.doc` for details) and call the subroutine `SETUP`. The main integration loop is:

```plaintext
do i=1,STEPS
  t = T0 + i*dt
  call UT(F,t,tstep,Y,YP,YMAX,WORK,UFLAG)
  if(UFLAG.GT.2) exit  ! exit the loop: go after enddo
  write(11,100) tstep,Y(1),Y(2),Y(3),Y(4),Y(5),Y(6),&
                     energy(tstep,Y)
endo
```

The function \( F \) is the subroutine that calculates the derivatives and it will be programmed by us later. The variable \( t \) stores the desired moment of time at which we want to calculate the functions. Because of the adaptive stepsize, it can be different than the one returned by the subroutine `UT`. The actual value of time that the next step lands on is \( \text{tstep} \). The array \( \text{Y} \) stores the values of the functions. We choose the data structure to be such that \( x=Y(1), y=Y(2), z=Y(3) \) and \( v_x=Y(4), v_y=Y(5), v_z=Y(6) \)

---

When \( \text{UFLAG} \leq 2 \), \( \text{tstep}=t \) and we will not worry about them being different with our program.
6.1. ADAPTIVE STEPSIZE CONTROL FOR RUNGE–KUTTA METHODS

(the same sequence as in the array YSTART). The function energy(t,Y) returns the value of the mechanical energy of the particle and its code will be written in the same file as that of F. Finally, the variable UFLAG indicates the error status of the calculation by UT and if UFLAG > 2 we end the calculation.

Our test code will be on the study of the motion of a projectile in a constant gravitational field, subject also to the influence of a dissipative force $\vec{F}_r = -mk\vec{v}$. The program is in the file rk3_g.f90. We choose the parameters $k_1$ and $k_2$ so that $\vec{g} = -k_1 \vec{k}$ and $k = k_2$.

```
subroutine F(T,Y,YP)
  include 'rk3.inc'
  real(8) :: t
  real(8) :: Y(*),YP(*)
  real(8) :: x1,x2,x3,v1,v2,v3
  x1 = Y(1);v1 = Y(4)
  x2 = Y(2);v2 = Y(5)

Time: Initial T0 = 0.0000E+000  Final TF = 3.0000
X1(T0)= 0.0000E+000  X2(T0)= 0.0000E+000
X3(T0)= 0.0000E+000  V1(T0)= 1.0000  V2(T0)= 1.0000
V3(T0)= 1.0000
> gnuplot
gnuplot> plot "rk3.dat" using 1:2 with lines title "x1(t)"
gnuplot> plot "rk3.dat" using 1:3 with lines title "x2(t)"
gnuplot> plot "rk3.dat" using 1:4 with lines title "x3(t)"
gnuplot> plot "rk3.dat" using 1:5 with lines title "v1(t)"
gnuplot> plot "rk3.dat" using 1:6 with lines title "v2(t)"
gnuplot> plot "rk3.dat" using 1:7 with lines title "v3(t)"
gnuplot> plot "rk3.dat" using 1:8 with lines title "E(t)"
gnuplot> set title "trajectory"
gnuplot> splot "rk3.dat" using 2:3:4 with lines notitle
```

All the above commands can be executed together using the shell script in the file rk3.csh. The script uses the animation script rk3_animate.csh. The following command executes all the commands shown above:

```
./rk3.csh -f 1 -- 10 0 0 0 0 0 1 1 1 10000 0 3
```

\(^6\)Note the declaration of the arrays Y, YP: real(8) :: Y(*),YP(*). These arrays are “assumed-size” arrays for the functions F, energy, i.e. arrays whose size is unknown to the procedure. For arrays of more than one dimension, only the last index is allowed to be *. In general it is recommended that assumed-size arrays be avoided and declare them as assumed-shape like in the program rkA.f90 of page 273. The declaration in this case is real(8) :: Y(:,),YP(,:)
6.2 Motion of a Particle in an EM Field

In this section we study the non-relativistic motion of a charged particle in an electromagnetic (EM) field. The particle is under the influence of the Lorentz force:

\[ \vec{F} = q(\vec{E} + \vec{v} \times \vec{B}). \] (6.2)

Consider the constant EM field of the form \( \vec{E} = E_x \hat{x} + E_y \hat{y} + E_z \hat{z}, \vec{B} = B \hat{z} \). The components of the acceleration of the particle are:

\[
\begin{align*}
    a_x &= (qE_x/m) + (qB/m)v_y \\
    a_y &= (qE_y/m) - (qB/m)v_x \\
    a_z &= (qE_z/m).
\end{align*}
\] (6.3)

This field is programmed in the file \texttt{rk3\_B.f90}. We set \( k_1 = qB/m \), \( k_2 = qE_x/m \), \( k_3 = qE_y/m \) and \( k_4 = qE_z/m \):

```fortran
! Particle in constant Magnetic and electric field
! q B/m = k1 z q E/m = k2 x + k3 y + k4 z
subroutine F(T,Y,YP)
  include 'rk3.inc'
  real(8) :: t
  real(8) :: Y(*),YP(*)
  real(8) :: x1,x2,x3,v1,v2,v3
  x1 = Y(1);v1 = Y(4)
  x2 = Y(2);v2 = Y(5)
  x3 = Y(3);v3 = Y(6)
! Velocities: dx_i/dt = v_i
  YP(1) = v1
  YP(2) = v2
  YP(3) = v3
! Acceleration: dv_i/dt = a_i
  YP(4) = k2 + k1 * v2
  YP(5) = k3 - k1 * v1
  YP(6) = k4
end subroutine F
```

```fortran
real(8) function energy(T,Y)
  include 'rk3.inc'
  real(8) :: t,e
  real(8) :: Y(*)
  real(8) :: x1,x2,x3,v1,v2,v3
  x1 = Y(1);v1 = Y(4)
  x2 = Y(2);v2 = Y(5)

Figure 6.1: The trajectory of a charged particle in a constant magnetic field \( \vec{B} = B\hat{z} \), where \( \frac{qB}{m} = 1.0 \), \( \vec{v}(0) = 1.0\hat{y} + 0.1\hat{z} \), \( \vec{r}(0) = 1.0\hat{x} \). The integration of the equations of motion is performed using the RK45 method from \( t_0 = 0 \) to \( t_f = 40 \) with 1000 steps.

We can also study space-dependent fields in the same way. The fields must satisfy Maxwell’s equations. We can study the confinement of a particle in a region of space by a magnetic field by taking \( \vec{B} = B_y\hat{y} + B_z\hat{z} \) with \( \frac{qB_y}{m} = -k_2y \), \( \frac{qB_z}{m} = k_1 + k_2z \) and \( qB_y/m = k_3z \), \( qB_z/m = k_1 + k_2y \). Note that \( \nabla \cdot \vec{B} = 0 \). You may also want to calculate the current density from the equation \( \nabla \times \vec{B} = \mu_0\vec{J} \).

The results are shown in figures 6.1–6.4.

6.3 Relativistic Motion

Consider a particle of non-zero rest mass moving with speed comparable to the speed of light. In this case, it is necessary to study its motion using
Figure 6.2: The trajectory of a charged particle in a constant magnetic field \( \vec{B} = B \hat{z} \),
where \( qB/m = 1.0 \) and a constant electric field \( \vec{E} = E_x \hat{x} + E_y \hat{y} \), \( qE_x/m = qE_y/m = 0.1 \),
\( \vec{v}(0) = 1.0 \hat{y} + 0.1 \hat{z} \), \( \vec{r}(0) = 1.0 \hat{x} \). The integration of the equations of motion is performed
using the RK45 method from \( t_0 = 0 \) to \( t_f = 40 \) with 1000 steps. Each axis is on a
different scale.

the equations of motion given by special relativity\(^7\). In the equations
below we set \( c = 1 \). The particle’s rest mass is \( m_0 > 0 \), its mass is
\( m = m_0/\sqrt{1 - v^2} \) (where \( v < 1 \)), its momentum is \( \vec{p} = m \vec{v} \) and its energy
is \( E = m = \sqrt{p^2 + m_0^2} \). Then the equations of motion in a dynamic field \( \vec{F} \) are given by:

\[
\frac{d\vec{p}}{dt} = \vec{F}. \tag{6.4}
\]

In order to write a system of first order equations, we use the relations

\[
\vec{v} = \frac{\vec{p}}{m} = \frac{\vec{p}}{E} = \frac{\vec{p}}{\sqrt{p^2 + m_0^2}}, \tag{6.5}
\]

\(^7\)Of course for lower speeds, the special relativity equations of motion are a better
approximation to the particle’s motion, but the corrections to the non relativistic equations
of motion are negligible.
CHAPTER 6. MOTION IN SPACE

Figure 6.3: The trajectory of a charged particle in a magnetic field \( \vec{B} = B_y \hat{y} + B_z \hat{z} \) with \( qB_y/m = -0.02y \), \( qB_z/m = 1 + 0.02z \), \( \vec{v}(0) = 1.0 \hat{y} + 0.1 \hat{z} \), \( \vec{r}(0) = 1.0 \hat{x} \). The integration of the equations of motion is performed using the RK45 method from \( t_0 = 0 \) to \( t_f = 500 \) with 10000 steps. Each axis is on a different scale.

Using \( \vec{v} = d\vec{r}/dt \) we obtain

\[
\begin{align*}
\frac{dx}{dt} &= \frac{(p_x/m_0)}{\sqrt{1 + (p/m_0)^2}}, & \frac{d(p_x/m_0)}{dt} &= \frac{F_x}{m_0} \\
\frac{dy}{dt} &= \frac{(p_y/m_0)}{\sqrt{1 + (p/m_0)^2}}, & \frac{d(p_y/m_0)}{dt} &= \frac{F_y}{m_0} \\
\frac{dz}{dt} &= \frac{(p_z/m_0)}{\sqrt{1 + (p/m_0)^2}}, & \frac{d(p_z/m_0)}{dt} &= \frac{F_z}{m_0}.
\end{align*}
\]  

(6.6)

which is a system of first order differential equations for the functions \( (x(t), y(t), z(t), (p_x/m_0)(t), (p_y/m_0)(t), (p_z/m_0)(t)) \). Given the initial conditions \( (x(0), y(0), z(0), (p_x/m_0)(0), (p_y/m_0)(0), (p_z/m_0)(0)) \) their solution is unique and it can be computed numerically using the 4th-5th order Runge–Kutta method according to the discussion of the previous section.
6.3. RELATIVISTIC MOTION

Figure 6.4: The trajectory of a charged particle in a magnetic field $\vec{B} = B_y \hat{y} + B_z \hat{z}$ with $qB_y/m = 0.08z$, $qB_z/m = 1.4 + 0.08y$, $\vec{v}(0) = 1.0\hat{y} + 0.1\hat{z}$, $\vec{r}(0) = 1.0\hat{x}$. The integration of the equations of motion is performed using the RK45 method from $t_0 = 0$ to $t_f = 3000$ with 40000 steps. Each axis is on a different scale.

By using the relations

\begin{align*}
(p_x/m_0) &= \frac{v_x}{\sqrt{1-v^2}} & v_x &= \frac{(p_x/m_0)}{\sqrt{1+(p/m_0)^2}} \\
(p_y/m_0) &= \frac{v_y}{\sqrt{1-v^2}} & v_y &= \frac{(p_y/m_0)}{\sqrt{1+(p/m_0)^2}} \\
(p_z/m_0) &= \frac{v_z}{\sqrt{1-v^2}} & v_z &= \frac{(p_z/m_0)}{\sqrt{1+(p/m_0)^2}},
\end{align*}

(6.7)

we can use the initial conditions $(x(0), y(0), z(0), v_x(0), v_y(0), v_z(0))$ instead. Similarly, from the solutions $(x(t), y(t), z(t), (p_x/m_0)(t), (p_y/m_0)(t), (p_z/m_0)(t))$ we can calculate $(x(t), y(t), z(t), v_x(t), v_y(t), v_z(t))$. We always have to check that

\begin{equation}
\begin{aligned}
v^2 &= (v_x)^2 + (v_y)^2 + (v_z)^2 < 1. \tag{6.8}
\end{aligned}
\end{equation}

Since half of the functions that we integrate for are the momentum instead of the velocity components, we need to make some modifications to the
program in the file rk3.f90. The main program can be found in the file sr.f90:

```

end subroutine velocity

!=================================================================================
!
!velocity -> momentum transformation
!=================================================================================

subroutine momentum(v1,v2,v3,p1,p2,p3)
The subroutines `momentum` and `velocity` compute the transformations (6.7). In the subroutine `momentum` we check whether the condition (6.8) is satisfied. These functions are also used in the subroutine `F` that computes the derivatives of the functions.

The test drive of the above program is the well known relativistic motion of a charged particle in a constant EM field. The acceleration of the particle is given by equations (6.3). The relativistic kinetic energy of the particle is

\[
T = \left(\frac{1}{\sqrt{1 - v^2}} - 1\right) m_0 = \left(\sqrt{1 + (p/m_0)^2} - 1\right) m_0 \quad (6.9)
\]

These relations are programmed in the file `sr_B.f90`. The contents of the file `sr_B.f90` are:

```fortran
!=================================================================
! Particle in constant Magnetic and Electric field
! q B/m = k1 z \quad q E/m = k2 x + k3 y + k4 z
!=================================================================

YP(6) = k4
```

6.3. RELATIVISTIC MOTION

end subroutine F
!

Energy per unit rest mass
!

real(8) function energy(T,Y)
include 'sr.inc'
real(8) :: t,e
real(8) :: Y(*)
real(8) :: x1,x2,x3,v1,v2,v3,p1,p2,p3,psq
x1 = Y(1); p1 = Y(4)
x2 = Y(2); p2 = Y(5)
x3 = Y(3); p3 = Y(6)
psq = p1*p1+p2*p2+p3*p3
! Kinetic Energy/m_0
e = sqrt(1.0D0+psq)-1.0D0
! Potential Energy/m_0
e = e - k2*x1 - k3*x2 - k4*x3
energy = e
end function energy

The results are shown in figures 6.5–6.6.

Figure 6.5: The trajectory of a relativistic charged particle in a magnetic field $B = B_z \hat{z}$ with $qB_z/m_0 = 10.0$, $\vec{v}(0) = 0.95\hat{y} + 0.10\hat{z}$, $\vec{r}(0) = 1.0\hat{x}$. The integration is performed by using the RK45 method from $t_0 = 0$ to $t_f = 20$ with 1000 steps. Each axis is on a different scale.
304  

CHAPTER 6. MOTION IN SPACE

Figure 6.6: Projection of the trajectory of a relativistic charged particle in a magnetic field \( \vec{B} = B_z \hat{z} \) with \( qB_z/m_0 = 10.0 \), on the \( xy \) plane. \( \vec{r}(0) = 0.95\hat{y} + 0.10\hat{z} \), \( \vec{r}(0) = 1.0\hat{x} \). The integration is performed by using the RK45 method from \( t_0 = 0 \) to \( t_f = 20 \) with 1000 steps. Each axis is on a different scale.

Now we can study a more interesting problem. Consider a simple model of the Van Allen radiation belt. Assume that the electrons are moving within the Earth’s magnetic field which is modeled after a magnetic dipole field of the form:

\[
\vec{B} = B_0 \left( \frac{R_E}{r} \right)^3 \left[ 3(\hat{d} \cdot \hat{r}) \hat{r} - \hat{d} \right], \tag{6.10}
\]

where \( \vec{d} = d\hat{d} \) is the magnetic dipole moment of the Earth’s magnetic field and \( \vec{r} = r\hat{r} \). The parameter values are approximately equal to \( B_0 = 3.5 \times 10^{-5} \text{T} \), \( r \sim 2R_E \), where \( R_E \) is the radius of the Earth. The typical energy of the moving particles is \( \sim 1 \text{ MeV} \) which corresponds to velocities of magnitude \( v/c = \sqrt{E^2 - m_0^2/E} \approx \sqrt{1 - 0.512^2}/1 = 0.86 \). We choose the coordinate axes so that \( \hat{d} = \hat{z} \) and we measure distance in \( R_E \) units.\(^8\) Then

\(^8\)Since \( c = 1 \), the unit of time is the time that the light needs to travel distance equal to \( R_E \) in the vacuum.
we obtain:

\[
\begin{align*}
B_x &= B_0 \frac{3xz}{r^5} \\
B_y &= B_0 \frac{3yz}{r^5} \\
B_z &= B_0 \left( \frac{3zz}{r^5} - \frac{1}{r^3} \right) 
\end{align*}
\] (6.11)

The magnetic dipole field is programmed in the file sr_Bd.f90:

The results are shown in figure 6.8. The parameters have been exaggerated in order to achieve an aesthetically pleasant result. In reality, the electrons are moving in very thin spirals and the reader is encouraged to use more realistic values for the parameters \( \vec{v}_0, B_0, \vec{r}_0 \). The problem of why the effect is not seen near the equator is left as an exercise.
6.4 Problems

6.1 Compute the trajectory of a projectile moving in space in a constant gravitational field and under the influence of an air resistance proportional to the square of its speed.

6.2 Two point charges are moving with non-relativistic speeds in a constant magnetic field $\vec{B} = B\hat{z}$. Assume that their interaction is given by the Coulomb force only. Write a program that computes their trajectory numerically using the RK45 method.

6.3 Write a program that computes the trajectory of the anisotropic harmonic oscillator $\vec{F} = -k_x x \hat{x} - k_y y \hat{y} - k_z z \hat{z}$. Compute the three dimensional Lissajous curves which appear for appropriate values of the angular frequencies $\omega_x = \sqrt{k_x/m}$, $\omega_y = \sqrt{k_y/m}$, $\omega_z = \sqrt{k_z/m}$.

6.4 Two particles of mass $M$ are at the fixed positions $\vec{r}_1 = a \hat{z}$ and $\vec{r}_2 = -a \hat{z}$. A third particle of mass $m$ interacts with them via a Newtonian gravitational force and moves at non-relativistic speeds.
Compute the particle’s trajectory and find initial conditions that result in a planar motion.

6.5 Solve problem 5.19 of page 283 using the RK45 method. Choose initial conditions so that the system executes only translational motion. Next, choose initial conditions so that the system executes small vibrations and its center of mass remains stationary. Find the normal modes of the system and choose appropriate initial conditions that put the system in each one of them.

6.6 Solve the previous problem by putting the system in a box $|x| \leq L$ and $|y| \leq L$.
   Hint: Look in the file springL.f90.

6.7 Solve the problem 5.20 in page 284 by using the RK45 method.
6.8 Solve the problem 5.21 in page 284 by using the RK45 method.

6.9 The electric field of an electric dipole $\vec{p} = p\hat{z}$ is given by:

$$\vec{E} = E_\rho \hat{\rho} + E_z \hat{z}$$

$$E_\rho = \frac{1}{4\pi\varepsilon_0} \frac{3\rho \sin \theta \cos \theta}{r^3}$$

$$E_z = \frac{1}{4\pi\varepsilon_0} \frac{p(3\cos^2 \theta - 1)}{r^3}$$

(6.12)

where $\rho = \sqrt{x^2 + y^2} = r \sin \theta$, $E_x = E_\rho \cos \phi$, $E_y = E_\rho \sin \phi$ and $(r, \theta, \phi)$ are the polar coordinates of the point where the electric field is calculated. Calculate the trajectory of a test charge moving in this field at non relativistic speeds. Calculate the deviation between the relativistic and the non relativistic trajectories when the initial speed is $0.01c, 0.1c, 0.5c, 0.9c$ respectively (ignore radiation effects).

6.10 Consider a linear charge distribution with constant linear charge density $\lambda$. The electric field is given by

$$\vec{E} = E_\rho \hat{\rho} = \frac{1}{4\pi\varepsilon_0} \frac{2\lambda}{\rho} \hat{\rho}$$

Calculate the trajectories of two equal negative test charges that move at non relativistic speeds in this field. Consider only the electrostatic Coulomb forces and ignore anything else.
6.4. PROBLEMS

6.11 Consider a linear charge distribution on four straight lines parallel to the $z$ axis. The linear charge density is $\lambda$ and it is constant. The four straight lines intersect the $xy$ plane at the points $(0, 0)$, $(0, a)$, $(a, 0)$, $(a, a)$. Calculate the trajectory of a non relativistic charge in this field. Next, compute the relativistic trajectories (ignore all radiation effects).

6.12 Three particles of mass $m$ interact via their Newtonian gravitational force. Compute their (non relativistic) trajectories in space.
Chapter 7

Electrostatics

In this chapter we will study the electric field generated by a static charge distribution. First we will compute the electric field lines and the equipotential surfaces of the electric field generated by a static point charge distribution on the plane. Then we will study the electric field generated by a continuous charge distribution on the plane. This requires the numerical solution of an elliptic boundary value problem which will be done using successive over-relaxation (SOR) methods.

7.1 Electrostatic Field of Point Charges

Consider \( N \) point charges \( Q_i \) which are located at fixed positions on the plane given by their position vectors \( \vec{r}_i \), \( i = 1, \ldots, N \). The electric field is given by Coulomb’s law

\[
\vec{E}(\vec{r}) = \frac{1}{4\pi \epsilon_0} \sum_{i=1}^{N} \frac{Q_i}{|\vec{r} - \vec{r}_i|^2} \hat{\rho}_i
\]  

(7.1)

where \( \hat{\rho}_i = (\vec{r} - \vec{r}_i)/|\vec{r} - \vec{r}_i| \) is the unit vector in the direction of \( \vec{r} - \vec{r}_i \). The components of the field are

\[
E_x(x, y) = \frac{1}{4\pi \epsilon_0} \sum_{i=1}^{N} \frac{Q_i(x - x_i)}{((x - x_i)^2 + (y - y_i)^2)^{3/2}}
\]

\[
E_y(x, y) = \frac{1}{4\pi \epsilon_0} \sum_{i=1}^{N} \frac{Q_i(y - y_i)}{((x - x_i)^2 + (y - y_i)^2)^{3/2}}.
\]  

(7.2)
The electrostatic potential at \( \vec{r} \) is
\[
V(\vec{r}) = V(x, y) = \frac{1}{4\pi\epsilon_0} \sum_{i=1}^{N} \frac{Q_i}{((x - x_i)^2 + (y - y_i)^2)^{1/2}}, \tag{7.3}
\]
and we have that
\[
\vec{E}(\vec{r}) = -\nabla V(\vec{r}). \tag{7.4}
\]

The electric field lines are the integral curves of the vector field \( \vec{E} \), i.e. the curves whose tangent lines at each point are parallel to the electric field at that point. The magnitude of the electric field is proportional to the density of the field lines (the number of field lines per perpendicular area). This means that the electric flux \( \Phi_E = \int_S \vec{E} \cdot d\vec{A} \) through a surface \( S \) is proportional to the number of field lines that cross the surface. Electric field lines of point charge distributions start from positive charges (sources), end in negative charges (sinks) or extend to infinity.

The equipotential surfaces are the loci of the points of space where the electrostatic potential takes fixed values. They are closed surfaces. Equation (7.4) tells us that a strong electric field at a point is equivalent to a strong spatial variation of the electric potential at this point, i.e. to dense equipotential surfaces. The direction of the electric field is perpendicular to the equipotential surfaces at each point\(^1\), which is the direction of the strongest spatial variation of \( V \), and it points in the direction of decreasing \( V \). The planar cross sections of the equipotential surfaces are closed curves which are called equipotential lines.

The computer cannot solve a problem in the continuum and we have to consider a finite discretization of a field line. A continuous curve is approximated by a large but finite number of small line segments. The basic idea is illustrated in figure 7.1. The small line segment \( \Delta l \) is taken in the direction of the electric field and we obtain
\[
\Delta x = \Delta l \frac{E_x}{E}, \quad \Delta y = \Delta l \frac{E_y}{E}, \tag{7.5}
\]
where \( E \equiv |\vec{E}| = \sqrt{E_x^2 + E_y^2} \).

In order to calculate the equipotential lines we use the property that they are perpendicular to the electric field at each point. Therefore, if \((\Delta x, \Delta y)\) is in the tangential direction of a field line, then \((-\Delta y, \Delta x)\) is

\(^1\)Since for every small displacement \( d\vec{r} \) along an equipotential surface the potential stays constant \( dV = 0 \), we have that \( 0 = dV = \nabla V \cdot d\vec{r} = -\vec{E} \cdot d\vec{r} \), which implies \( \vec{E} \perp d\vec{r} \).
7.1. ELECTROSTATIC FIELD OF POINT CHARGES

Figure 7.1: The electric field is tangent at each point of an electric field line and perpendicular to an equipotential line. By approximating the continuous curve by the line segment $\Delta l$, we have that $\Delta y/\Delta x = E_y/E_x$.

in the perpendicular direction since $(\Delta x, \Delta y) \cdot (-\Delta y, \Delta x) = -\Delta x \Delta y + \Delta y \Delta x = 0$. Therefore the equations that give the equipotential lines are

$$
\Delta x = -\Delta l \frac{E_y}{E}, \quad \Delta y = \Delta l \frac{E_x}{E}.
$$

(7.6)

The algorithm that will allow us to perform an approximate calculation of the electric field lines and the equipotential lines is the following: Choose an initial point that belongs to the (unique) line that you want to draw. The electric field can be calculated from the known electric charge distribution and equation (7.2). By using a small enough step $\Delta l$ we move in the direction $(\Delta x, \Delta y)$ to the new position

$$
x \rightarrow x + \Delta x, \quad y \rightarrow y + \Delta y,
$$

(7.7)

where we use equations (7.5) or (7.6). The procedure is repeated until the drawing is finished. The programmer sets a criterion for that, e.g. when the field line steps out of the drawing area or approaches a charge closer than a minimum distance.
7.2 The Program – Appetizer and ... Desert

The hurried, but slightly experienced reader may skip the details of this section and go directly to section 7.4. There she can find the final form of the program and brief usage instructions.

In order to program the algorithm described in the previous section, we will separate the algorithmic procedures into four different but well defined tasks:

- **Main program**: The data structure, which is given by the position of the charges stored in the arrays \( X(P) \), \( Y(P) \) and the charges stored in the array \( Q(P) \), is defined. It also contains the user interface which consists of reading data entered by the user, like the number of charges \( N \), their positions and magnitude. Then the calculation of a group of field or equipotential lines is performed by calling the routines `eline` or `epotline` respectively.

  - **subroutine eline(xin,yin,X,Y,Q,N)**: Calculates the electric field line passing through the point \( xin,yin \). On entry, the user inputs the point \( xin,yin \) and the data \( N, X(N), Y(N), Q(N) \). On exit, the subroutine prints to the `stdout` the coordinates of the approximate electric field line. The line extends up to a point that is either too close to one of the point charges or until the line leaves the drawing area. It calls the subroutines `efield` for the calculation of the electric field and `mdist` for the calculation of the minimum and maximum distance of a point on the field line from all the point charges.

  - **subroutine epotline(xin,yin,X,Y,Q,N)**: Calculates the equipotential line passing through the point \( xin,yin \). On entry, the user inputs the point \( xin,yin \) and the data \( N, X(N), Y(N), Q(N) \). On exit, the subroutine prints to the `stdout` the coordinates of the approximate equipotential line. The subroutine stops calculating an equipotential line when it comes back close enough to the original point \( xin,yin \) or when it leaves the drawing area. It calls the subroutines `efield` for the calculation of the electric field and `mdist` for the calculation of the minimum and maximum distance of a point on the equipotential line from all the point charges.

\(^2\)Remember that field lines start at sources, end at sinks or extend to infinity.
\(^3\)Remember that the equipotential lines are closed.
7.2. THE PROGRAM – APPETIZER AND ... DESERT

- subroutine efield(x0,y0,X,Y,Q,N,Ex,Ey): Calculates the electric field Ex, Ey at position x0, y0. On entry, the user provides the number of charges N, the position of charges X(N), Y(N), the charges Q(N) and the position x0, y0. On exit, the routine provides the values Ex, Ey.

- subroutine mdist(x0,y0,X,Y,N,rmin,rmax): Calculates the maximum and minimum distance of the point x0, y0 from all charges located at X(N), Y(N). On entry, the user provides the number of charges N, the position of charges X(N), Y(N) and the point x0, y0. On exit, the routine provides the minimum and maximum distances rmin,rmax.

In the main program, the variables N, X(N), Y(N) and Q(N) must be set. These can be hard coded by the programmer or entered by the user interactively. The first choice is coded in the program listed below, which can be found in the file ELines.f90. This is version 1 of the main program:

```
!********************************************************************
program Electric_Fields
!********************************************************************
implicit none
integer, parameter :: P=20 !max number of charges
real, dimension(P) :: X,Y,Q
integer :: N

!!----------------- SET CHARGE DISTRIBUTION -----
N  =  2
X(1) = 1.0
Y(1) = 0.0
Q(1) = 1.0
X(2) = -1.0
Y(2) = 0.0
Q(2) = -1.0

!!----------------- DRAWING LINES ----------------
call eline(0.0, 0.5,X,Y,Q,N)
call eline(0.0, 1.0,X,Y,Q,N)
call eline(0.0, 1.5,X,Y,Q,N)
call eline(0.0, 2.0,X,Y,Q,N)
call eline(0.0,-0.5,X,Y,Q,N)
call eline(0.0,-1.0,X,Y,Q,N)
call eline(0.0,-1.5,X,Y,Q,N)
call eline(0.0,-2.0,X,Y,Q,N)
end program Electric_Fields
```
The commands

```plaintext
!----------------- SET CHARGE DISTRIBUTION -------
N = 2
X(1) = 1.0
Y(1) = 0.0
Q(1) = 1.0
X(2) = -1.0
Y(2) = 0.0
Q(2) = -1.0
```

define two opposite charges \( Q(1)= -Q(2)= 1.0 \) located at \((1, 0)\) and \((-1, 0)\) respectively. The next lines call the subroutine `eline` in order to perform the calculation of 8 field lines passing through the points \((0, \pm 1/2)\), \((0, \pm 1)\), \((0, \pm 3/2)\), \((0, \pm 2)\):

```plaintext
!----------------- DRAWING LINES -------------------
call eline(0.0, 0.5,X,Y,Q,N)
call eline(0.0, 1.0,X,Y,Q,N)
call eline(0.0, 1.5,X,Y,Q,N)
call eline(0.0, 2.0,X,Y,Q,N)
call eline(0.0,-0.5,X,Y,Q,N)
call eline(0.0,-1.0,X,Y,Q,N)
call eline(0.0,-1.5,X,Y,Q,N)
call eline(0.0,-2.0,X,Y,Q,N)
```

These commands print the coordinates of the field lines to the stdout and the user can analyze them further.

The program for calculating the equipotential lines is quite similar. The calls to the subroutine `eline` are substituted by calls to `epotline`.

For the program to be complete, we must program the subroutines `eline`, `efield`, `mdist`. This will be done later, and you can find the full code in the file `ELines.f90`. For the moment, let’s copy the main program\(^4\) listed above into the file `Elines.f90` and compile and run it with the commands:

```bash
> gfortran ELines.f90 -o el
> ./el > el.out
```

The stdout of the program is redirected to the file `el.out`. We can plot the results with gnuplot:

\(^4\)See the file `ELines_version0.f90`. 

---
7.2. THE PROGRAM – APPETIZER AND ... DESERT

The result is shown in figure 7.2.

Figure 7.2: Some electric field lines of the electric field of two opposite charges calculated by the program ELines.f90 (version 1).

Let’s modify the program so that the user can enter the charge distribution, as well as the number and position of the field lines that she wants to draw, interactively. The part of the code that we need to change is:

```fortran
!------------------ SET CHARGE DISTRIBUTION ------------------
print *, '# Enter number of charges:'
read *, N
print *, '# N= ', N
do i=1,N
   print *, '# Charge: ', i
   print *, '# Position and charge: (X,Y,Q):'
   read *, X(i),Y(i),Q(i)
   print *, '# (X,Y)= ', X(i),Y(i), ' Q= ', Q(i)
enddo
```

The first line asks the user to enter the number of charges in the distribution. It proceeds with reading it from the stdin and prints the result...
CHAPTER 7. ELECTROSTATICS

to the stdout. The following loop reads the positions and charges and stores them at the position \( i \) of the arrays \( X(i), Y(i), Q(i) \). The results are printed to the stdout so that the user can check the values read by the program.

The drawing of the field lines is now done by modifying the code so that:

```fortran
!----------------- DRAWING LINES -----------------
p * , '# How many lines to draw? 
read * , draw
do i = 1 , draw
   p * , '# Initial point \((x_0,y_0)\):
   read * , x0 , y0
   call eline(x0 , y0 , X , Y , Q , N)
endo
```

As a test case, we run the program for one charge \( q = 1.0 \) located at the origin and we draw one field line passing through the point \((0.1, 0.1)\).

```
> gfortran ELines.f90 -o el
> ./el
# Enter number of charges: 1
# N= 1
# Charge: 1
# Position and charge: \((X,Y,Q)\):
 0.0 0.0 1.0
# \((X,Y)\)= 0.000000 0.000000 \(Q= 1.000000\)
# How many lines to draw? 1
# Initial point \((x_0,y_0)\):
 0.1 0.1
 9.2928931E-02 9.2928931E-02
 8.5857861E-02 8.5857861E-02
 7.8786790E-02 7.8786790E-02
....
```

For charge distributions with a large number of point charges, use an editor to record the charges, their positions and the points where the field lines should go through.

```
2
 N: Number of Charges
 1.0 0.0 1.0 \((X,Y,Q)\): Position and charge
 -1.0 0.0 -1.0 \((X,Y,Q)\): Position and charge
 8 Number of lines to draw
```
0.0 0.5 x0,y0: Initial point of line
0.0 1.0 x0,y0: Initial point of line
0.0 1.5 x0,y0: Initial point of line
0.0 2.0 x0,y0: Initial point of line
0.0 −0.5 x0,y0: Initial point of line
0.0 −1.0 x0,y0: Initial point of line
0.0 −1.5 x0,y0: Initial point of line
0.0 −2.0 x0,y0: Initial point of line

If the data listed above is written into a file, e.g. Input, then the command

```
./el < Input > el.out
```

reads the data from the file Input and redirects the data printed to the stdout to the file el.out. This way you can create a “library” of charge distributions and the field lines of their respective electric fields. The complete code (version 2) is listed below:

```
!***********************************************************************
program Electric_Fields
!***********************************************************************
implicit none
integer, parameter :: P=20 !max number of charges
real,dimension(P) :: X,Y,Q
integer :: N
integer :: i,j,draw
real :: x0,y0
!
!--------------------- SET CHARGE DISTRIBUTION ---------------------
print *, ' # Enter number of charges:'
read *, N
print *, ' # N= ', N
do i=1,N
   print *, ' # Charge: ', i
   print *, ' # Position and charge: (X,Y,Q):'
   read *, X(i),Y(i),Q(i)
   print *, ' # (X,Y)= ', X(i),Y(i), ' Q= ', Q(i)
enddo
!
!--------------------- DRAWING LINES ---------------------
!
print *, ' # How many lines to draw? '
read *, draw
do i=1,draw
   print *, ' # Initial point (x0,y0): '
   read *, x0,y0
   call eline(x0,y0,X,Y,Q,N)
enddo
end program Electric_Fields
```
If you did the exercises described above, you should have already realized that in order to draw a nice representative picture of the electric field can be time consuming. For field lines one can use simple physical intuition in order to automate the procedure. For distances close enough to a point charge the electric field is approximately isotropic. The number of field lines crossing a small enough curve which contains only the charge is proportional to the charge (Gauss’s law). Therefore we can draw a small circle centered around each charge and choose initial points isotropically distributed on the circle as initial points of the field lines. The code listed below (version 3) implements the idea for charges that are equal in magnitude. For charges different in magnitude, the program is left as an exercise to the reader.

```fortran
program Electric_Fields

implicit none
integer , parameter :: P=20 !max number of charges
real , dimension(P):: X,Y,Q
integer :: N
integer :: i,j,nd
real :: x0,y0,theta
real , parameter :: PI= 3.14159265359

! ---------------- SET CHARGE DISTRIBUTION ----------------
print *, '# Enter number of charges:'
read *, N
print *, '# N= ',N
do i=1,N
  print *, '# Charge: ',i
  print *, '# Position and charge: (X,Y,Q):'
  read *, X(i),Y(i),Q(i)
  print *, '# (X,Y)= ', X(i),Y(i), ' Q= ',Q(i)
enddo

! ---------------- DRAWING LINES ----------------
!We draw 2*nd field lines around each charge
nd = 6
do i = 1,N
  do j = 1,(2*nd)
    theta = (PI/nd)*j
    x0 = X(i) + 0.1 * cos(theta)
    y0 = Y(i) + 0.1 * sin(theta)
    call eline(x0,y0,X(i),Y(i),Q(i),N)
  enddo
enddo
```
We set the number of field lines around each charge to be equal to 12 (nd=6). The initial points are taken on the circle whose center is \((X(i),Y(i))\) and its radius is 0.1. The 2*nd points are determined by the angle \(\theta = (\pi/\text{nd}) \cdot j\).

We record the data of a charge distribution in a file, e.g. Input. Below, we list the example of four equal charges \(q_i = \pm 1\) located at the vertices of a square:

<table>
<thead>
<tr>
<th>N</th>
<th>Number of charges</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
<tr>
<td>-1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
<tr>
<td>1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
<tr>
<td>-1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
</tbody>
</table>

Then we give the commands:

```bash
> gfortran ELines.f90 -o el
> ./el < Input > el.out
> gnuplot
```

The results are shown in figures 7.3 and 7.4. The reader should determine the charge distributions that generate those fields and reproduce the figures as an exercise.

For the computation of the equipotential lines we can work in a similar way. We will follow a quick and dirty way which will not produce an accurate picture of the electric field and choose the initial points evenly spaced on an square lattice. For a better choice see problem 5. The listed code is in the file EPotential.f90:

```fortran
program Electric_Potential
!
implicit none
integer, parameter :: P=20 !max number of charges
real, dimension(P) :: X,Y,Q
integer :: N
real, parameter :: PI= 3.14159265359
integer :: i,j,nd
real :: x0,y0,rmin,rmax,L
!
print *, '# Enter number of charges:'
```
Figure 7.3: Field lines of a static charge distribution of point charges generated by the program ELines.f90.

```fortran
! We draw lines passing through an equally
! spaced lattice of N=(2*nd+1)x(2*nd+1) points
! in the square -L<= x <= L, -L<= y <= L.
nd   = 4
L    = 1.0
do  i = -nd, nd
    do j = -nd, nd
        x0 = i*(L/nd)
y0  = j*(L/nd)
        print *, '# @ ', i, j, L/nd, x0, y0
        call mdist(x0,y0,X,Y,N,rmin,rmax)
        if(rmin .gt. L/(nd*10))&
            call epotline(x0,y0,X,Y,Q,N)
```
7.3. *THE PROGRAM – MAIN DISH*

In this section we look under the hood and give the details of the inner parts of the program: The subroutines *eline* and *epotline* that calculate the field and equipotential lines, the subroutine *efield* that calculates the electric field at a point and the subroutine *mdist* that calculates the

```fortran
enddo
enddo
end program Electric_Potential
```

The first and second part of the code is identical to the previous one. In the third part we call the subroutine *epotline* for drawing an equipotential line for each initial point. The initial points are on a square lattice with \((2*nd+1)*(2*nd+1)= 81\) points \((nd=4)\). The lattice extends within the limits set by the square \((1,1); (-1,1); (-1,-1); (1,-1) (L=1.0)\). For each point \((x_0,y_0)\) we calculate the equipotential line that passes through it. We check that this point is not too close to one of the charges by calling the subroutine *mdist*. The call determines the minimum distance \(r_{\text{min}}\) of the point from all the charges which should be larger than \(L/(nd*10)\). You can run the program with the commands:

```
> gfortran EPotential.f90 -o ep
> ./ep < Input > ep.out
> gnuplot
> gnuplot> plot "ep.out" with dots
```

Some of the results are shown in figure 7.5.

Figure 7.4: Field lines of a static charge distribution of point charges generated by the program ELines.f90.
Figure 7.5: Equipotential lines of the electric field generated by a point charge distribution on the plane calculated by the program in EPotential.f90. Beware: the density of the lines is not correctly calculated and it is not proportional to the magnitude of the electric field. See problem 7.5.

minimum and maximum distances of a point from the point charges.

The subroutine eLine is called by the command:

```
call eLine(x0, y0, X, Y, Q, N)
```

The input to the routine is the initial point \((x_0, y_0)\), the number of charges \(N\), the positions of the charges \((X(N), Y(N))\) and the charges \(Q(N)\). The routine needs some parameters in order to draw the field line. These are “hard coded”, i.e. set to fixed values by the programmer that cannot be changed by the user that calls the routine in her program. One of them is the step \(\Delta l\) of equation (7.5) which sets the discretization step of the field line. It also sets the minimum distance of approaching to a charge equal to \(2\Delta l\). The size of the drawing area of the curve is set by the parameter \(\text{max\_dist}=20.0\). We should also provide a check in the program that checks whether the electric field is zero, in which case the result of the calculation in equation (7.5) becomes indeterminate. By taking \(\Delta l > 0\), the motion is in the direction of the electric field, which ends on a negative charge or outside the drawing area (why?). In order
to draw the line in both directions, set $\Delta l < 0$ and repeat the calculation.

The code is listed below:

```fortran
! *****************************************************
subroutine eline(xin,yin,X,Y,Q,N)
! *****************************************************
implicit none
integer :: N
real, dimension(N) :: X,Y,Q
real :: xin,yin,x0,y0
real, parameter :: step=0.01
real, parameter :: max_dist=20.0
integer :: i,direction
real :: rmin,rmax,r,dx,dy,dl
real :: Ex,Ey,E

do direction = -1,1,2
  ! direction= +/- 1
  dl = direction * step
  x0 = xin

    print *,x0,y0
    ! We evaluate the E-field at the midpoint: This reduces
    ! systematic errors
    call efield(x0+0.5*dx,y0+0.5*dy,X,Y,Q,N,Ex,Ey)
    E = sqrt(Ex*Ex+Ey*Ey)
    if( E .le. 1.0e-10 ) exit
    dx = dl*Ex/E
    dy = dl*Ey/E
    x0 = x0 + dx
    y0 = y0 + dy
    call mdist(x0,y0,X,Y,N,rmin,rmax)
  enddo
  !do while()
enddo
! do direction = -1,1,2
end subroutine eline
```

In the first part of the code we have the variable declarations. We only note the declaration

```fortran
real, dimension(N) :: X,Y,Q
```

which declares the dimension of the arrays to be $N$ instead of their true dimension $P$. This is fine, as long as the programmer of the calling program has already checked that $N \leq P$. The necessary memory for the
arrays is allocated in the calling program and the declaration does not provide new storage space. The arrays \( X, Y, Q \) are passed to the subroutine “by reference”, i.e. the routine learns about their position in the memory to which it can refer to, and not “by value”. The parameters \( \Delta l = \text{step} \) and \( \text{max_dist} \) are fixed by the parameter attribute:

\[
\begin{align*}
\text{real parameter} &:: \text{step}=0.01 \\
\text{real parameter} &:: \text{max_dist}=20.0
\end{align*}
\]

Their values should be the result of a careful study by the programmer since they determine the accuracy of the calculation.

The outmost loop

\[
\begin{align*}
do & \text{ direction } = -1,1,2 \\
dl & = \text{ direction } \times \text{step} \\
\ldots
\end{align*}
\]

sets the direction of motion on the field line (i.e. the sign of \( \Delta l \)). The command \( \text{do direction } = -1,1,2 \) executes the loop twice by setting the variable direction to take values from \(-1\) to \(1\) with step equal to \(2\).

The commands \( x_0 = xin, y_0 = yin \) define the initial point on the field line. \((x_0, y_0)\) is the current point on the field line which is printed to the stdout with the command print. The variables \((dx, dy)\) set the step \( (x_0, y_0) \rightarrow (x_0+dx, y_0+dy) \). The drawing of the field line is done in the inner loop

\[
\begin{align*}
call & \text{mdist}(x_0,y_0,X,Y,N,\text{rmin}.rmax) \\
\text{do while} & (\text{rmin} > (2.0\times\text{step}) \text{.and. rmax} < \text{max_dist}) \\
\ldots
\end{align*}
\]

which is executed provided that the logical expression \((\text{rmin} > (2.0\times\text{step}) \text{.and. rmax} < \text{max_dist})\) is \(\text{.TRUE.}\). This happens as long as the current point is at a distance greater than \(2.0\times\text{step}\) and the maximum distance from all charges is less than \(\text{max_dist}\). The minimum and maximum distances are calculated by calling the subroutine \text{mdist}.

The electric field, needed in equation \((7.5)\), is calculated by a call to \(\text{efield}(x_0+0.5\times dx, y_0+0.5\times dy, X, Y, Q, N, E_x, E_y)\). The first two arguments give the point at which we want to calculate the electric field, which is

\[^5\text{The choice is not unique of course, you may also try e.g. rmin .lt. max_dist.}\]
chosen to be the midpoint \((x_0+dx/2, y_0+dy/2)\) instead of \((x_0, y_0)\). This improves the stability and the accuracy of the algorithm.

Equation (7.5) is coded in the commands

\[
\begin{align*}
E &= \sqrt{Ex^2 + Ey^2} \\
xd &= d1 \times Ex / E \\
yd &= d1 \times Ey / E \\
x0 &= x0 + dx \\
y0 &= y0 + dy
\end{align*}
\]

We also perform checks for the cases \(E=0.0\) and \(dx=dy=0.0\):

\[
\text{if ( E .le. 1.0e-10 ) exit}
\]

When the magnitude of the electric field becomes too small we stop the calculation by exiting the loop with the command exit. The reader can improve the code by adding more checks of singular cases.

The subroutine `epotline` is programmed in a similar way. The relevant code is listed below:

```fortran
!**********************************************************************
subroutine epotline(xin,yin,X,Y,Q,N)
!**********************************************************************
implicit none
integer :: N
real, dimension(N) :: X,Y,Q
real :: xin,yin,x0,y0
real, parameter :: step=0.02
real, parameter :: max_dist=20.0
integer :: i
real :: r,dx,dy,d1
real :: Ex,Ey,E

d1 = step
x0 = xin
y0 = yin
dx = 0.0
dy = 0.0
r = step !in order to start loop
do while( r .gt. (0.9*d1) .and. r .lt. max_dist)
   print *,x0,y0
! We evaluate the E-field at the midpoint: This reduces!
   systematic errors
   call efield(x0+0.5*dx,y0+0.5*dy,X,Y,Q,N,Ex,Ey)
   E = sqrt(Ex*Ex+Ey*Ey)
```

```
The differences are minor: The equipotential lines are closed curves, therefore we only need to transverse them in one direction. The criterion for ending the calculation is to approach the initial point close enough or leave the drawing area:

\[
\text{do while ( } r \text{.gt. (0.9*dl) .and. r .lt. max_dist) }
\]

\[
... 
\]

\[
\text{enddo}
\]

The values of \( \text{dx, dy} \) are calculated according to equation (7.6):

\[
\text{dx} = \text{dl} \ast \text{Ey}/E \\
\text{dy} = -\text{dl} \ast \text{Ex}/E
\]

The subroutine \texttt{efield} is an application of equations (7.2):

\[
\text{!} \text{******************************************************} \\
\text{subroutine efield(x0,y0,X,Y,Q,N,Ex,Ey)} \\
\text{!} \text{******************************************************} \\
\text{implicit none} \\
\text{integer} \\
\text{:: } N \\
\text{real,dimension(N)} :: X,Y,Q \\
\text{real} \\
\text{:: } x0,y0,dx,dy,Ex,Ey \\
\text{integer} \\
\text{:: } i \\
\text{real} \\
\text{:: } r3,xi,yi \\
\text{Ex} = 0.0 \\
\text{Ey} = 0.0 \\
\text{do i= 1,N} \\
\text{xi = x0-X(i)} \\
\text{yi = y0-Y(i)} \\
\text{r3 = (xi*xi+yi*yi)**(-1.5)} \\
\text{Ex = Ex + Q(i)*xi*r3} \\
\text{Ey = Ey + Q(i)*yi*r3} \\
\text{enddo}
\]

*You may improve the program by checking whether \( r_i = 0 \).*
Finally, the subroutine mdist calculates the minimum and maximum distance \( r_{min} \) and \( r_{max} \) of a point \((x_0, y_0)\) from all the point charges in the distribution:

```fortran
subroutine mdist(x0, y0, X, Y, N, rmin, rmax)

! Initial value of rmin depends on the limits of the drawing area (why?).
```

7.4 The Program - Conclusion

In this section we list the programs discussed in the previous sections and provide short usage information for compiling, running and analyzing your results. You can jump into this section without reading the previous ones and go back to them if you need to clarify some points that you find hard to understand.

First we list the contents of the file ELines.f90:
real :: x0, y0, theta
real, parameter :: PI = 3.14159265359

!------------------ SET CHARGE DISTRIBUTION ------------------
print *, '# Enter number of charges:'
read *, N
print *, '# N= ', N
do i=1,N
  print *, '# Charge: ', i
  print *, '# Position and charge: (X,Y,Q):'
  read *, X(i), Y(i), Q(i)
  print *, '# (X,Y)= ', X(i), Y(i), ' Q= ', Q(i)
enddo

!---------------- DRAWING LINES -----------------
We draw 2*nd field lines around each charge
nd = 6
do i = 1,N
do j = 1, (2*nd)
theta = (PI/nd)*j
x0 = X(i) + 0.1 * cos(theta)
y0 = Y(i) + 0.1 * sin(theta)
call eline(x0, y0, X, Y, Q, N)
enddo
endo
end program Electric_Fields

!-----------------------------------------------------------
subroutine eline(xin,yin,X,Y,Q,N)
!-----------------------------------------------------------
implicit none
integer :: N
real, dimension(N) :: X,Y,Q
real :: xin, yin, x0, y0
real, parameter :: step=0.01
real, parameter :: max_dist=20.0
integer :: i, direction
real :: rmin, rmax, r, dx, dy, dl
real :: Ex, Ey, E

do direction = -1,1,2
  !direction= +/- 1
  dl = direction * step
  x0 = xin
  y0 = yin
dx = 0.0
dy = 0.0
  call mdist(x0, y0, X, Y, N, rmin, rmax)
do while (rmin .gt. (2.0*step) .and. rmax .lt. max_dist)
    print *, x0, y0
  ! We evaluate the E-field at the midpoint: This reduces
  ! systematic errors
    call efield(x0+0.5*dx, y0+0.5*dy, X, Y, N, Ex, Ey)
    E = sqrt(Ex*Ex+Ey*Ey)
enddo
end subroutine eline
if ( E .le. 1.0e-10 ) exit

dx = dl*Ex/E
dy = dl*Ey/E
x0 = x0 + dx
y0 = y0 + dy
call mdist(x0,y0,X,Y,N,rmin,rmax)
enddo ! do while()
enddo ! do direction = -1.12
end subroutine eline

!*************************************************************************
subroutine efield(x0,y0, X,Y,Q,N,Ex,Ey)
!*************************************************************************
implicit none
integer :: N
real, dimension(N) :: X,Y,Q
real :: x0,y0,dx,dy,Ex,Ey
integer :: i
real :: r3,xi,yi

Ex = 0.0
Ey = 0.0

rmax = 0.0
rmin = 1000.0
do i= 1,N
r = sqrt((x0-X(i))**2 + (y0-Y(i))**2)
if(r.GT.rmax) rmax = r
if(r.LT.rmin) rmin = r
endo
dend subroutine mdist
Then we list the contents of the file EPotential.f90:

```fortran
program Electric_Potential
implicit none
integer parameter :: P=20 !max number of charges
real dimension(P) :: X,Y,Q
integer :: N
integer parameter :: PI= 3.14159265359
integer :: i,j,nd
real :: x0,y0,rmin,rmax,L

print *, '# Enter number of charges:'
read * , N
print *, '# N= ',N
do i=1,N
  print *, '# Charge: ',i
  print *, '# Position and charge: (X,Y,Q):'
  read * , X(i),Y(i),Q(i)
  print *, '# (X,Y)= ',X(i),Y(i), ' Q= ',Q(i)
enddo
!
! DRAWING LINES
! We draw lines passing through an equally spaced lattice of N=(2*nd+1)x(2*nd+1) points
! in the square -L<= x <= L, -L<= y <= L.
nd = 4
L = 1.0
do i = -nd,nd
  do j = -nd,nd
    x0 = i*(L/nd)
y0 = j*(L/nd)
    print *, '# @ ',i,j,L/nd,x0,y0
    call mdist(x0,y0,X,Y,N,rmin,rmax)
  enddo
enddo
!
!
end program Electric_Potential
!

subroutine epotline(xin,yin,X,Y,Q,N)
implicit none
integer :: N
real dimension(N) :: X,Y,Q
real :: xin,yin,x0,y0
real parameter :: step=0.02
!
!
end subroutine epotline
```
real, parameter :: max_dist = 20.0
integer :: i
real :: r, dx, dy, dl
real :: Ex, Ey, E

dl = step
x0 = xin
y0 = yin
dx = 0.0
dy = 0.0
r = step
! in order to start loop
do while (r .gt. (0.9*dl) .and. r .lt. max_dist)
  print *, x0, y0
! We evaluate the E-field at the midpoint: This reduces ! systematic errors
  call efield(x0+0.5*dx, y0+0.5*dy, X, Y, Q, N, Ex, Ey)
  E = sqrt(Ex*Ex+Ey*Ey)
  if (E .le. 1.0e-10) exit
  dx = dl*Ey/E
  dy = -dl*Ex/E
  x0 = x0 + dx
  y0 = y0 + dy
  r = sqrt((x0-xin)**2+(y0-yin)**2)
enddo
end subroutine epotline

where ... are the subroutines efield and mdist which are identical to
the ones in the file ELines.f90.

In order to compile the program use the commands:

> gfortran ELines.f90 -o el
> gfortran EPotential.f90 -o ep

Then, edit a file and name it e.g. Input and write the data that define a
charge distribution. For example:

<table>
<thead>
<tr>
<th>4</th>
<th>N: Number of charges</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 1 -1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
<tr>
<td>-1 1 1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
<tr>
<td>1 -1 1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
<tr>
<td>-1 -1 -1</td>
<td>(X,Y,Q): Position and charge</td>
</tr>
</tbody>
</table>

The results are obtained with the commands:

> ./el < Input > el.dat
7.5 Electrostatic Field in the Vacuum

Consider a time independent electric field in an area of space which is empty of electric charge. Maxwell’s equations are reduced to Gauss’s law

$$\nabla \cdot \vec{E}(x,y,z) = \frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} + \frac{\partial E_z}{\partial z} = 0,$$

(7.8)

together with the equation that defines the electrostatic potential\(^{3}\)

$$\vec{E}(x,y,z) = -\nabla V(x,y,z).$$

(7.9)

Equations (7.8) and (7.9) give the Laplace equation for the function \(V(x,y,z)\):

$$\nabla^2 V(x,y,z) = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0.$$

(7.10)

The solution of the equation above is a boundary value problem: We are looking for the potential \(V(x,y,z)\) in a region of space \(S\) bounded by a closed surface \(\partial S\). When the potential is known on \(\partial S\) the solution to (7.10) is unique and the potential and the electric field is determined everywhere in \(S\).

For simplicity consider the problem confined on a plane, therefore \(V = V(x,y)\). In this case the last term in equation (7.10) vanishes, the region \(S\) is a compact subset of the plane and \(\partial S\) is a closed curve.

For the numerical solution of the problem, we approximate \(S\) by a discrete, square lattice. The potential is defined on the \(N\) sites of the lattice. We take \(S\) to be bounded by a square with sides of length \(l\). The distance between the nearest lattice points is called the lattice constant \(a\). Then \(l = (L-1)a\), where \(L = \sqrt{N}\) is the number of lattice points on each side of the square. The continuous solution is approximated by the solution on the lattice, and the approximation becomes exact in the \(N \to \infty\) and \(a \to 0\) limits, so that the length \(l = (L-1)a\) remains constant. The curve \(\partial S\) is approximated by the lattice sites that are located on the

---

\(^3\)Equivalent to the equation \(\nabla \times \vec{E} = 0\).
perimeter of the square and the loci in the square where the potential takes constant values. This is a simple model of a set of conducting surfaces (points where \( V = \text{const.} \neq 0 \)) in a compact region whose boundary is grounded (points where \( V = 0 \)). An example is depicted in figure 7.6.

Figure 7.6: A lattice which corresponds to a cross section of two parallel conducting planes inside a grounded cubic box. The black lattice sites are the points of constant, fixed potential whereas the white ones are sites in the vacuum.

In order to derive a finite difference equation which approximates equation (7.10), we Taylor expand around a point \((x, y)\) according to the equations:

\[
\begin{align*}
V(x + \delta x, y) &= V(x, y) + \frac{\partial V}{\partial x} \delta x + \frac{1}{2} \frac{\partial^2 V}{\partial x^2} (\delta x)^2 + \ldots \\
V(x - \delta x, y) &= V(x, y) - \frac{\partial V}{\partial x} \delta x + \frac{1}{2} \frac{\partial^2 V}{\partial x^2} (\delta x)^2 + \ldots \\
V(x, y + \delta y) &= V(x, y) + \frac{\partial V}{\partial y} \delta y + \frac{1}{2} \frac{\partial^2 V}{\partial y^2} (\delta y)^2 + \ldots \\
V(x, y - \delta y) &= V(x, y) - \frac{\partial V}{\partial y} \delta y + \frac{1}{2} \frac{\partial^2 V}{\partial y^2} (\delta y)^2 + \ldots.
\end{align*}
\]

By summing both sides of the above equations, taking \( \delta x = \delta y \) and
ignoring the terms implied by \( \ldots \), we obtain
\[
V(x + \delta x, y) + V(x - \delta x, y) + V(x, y + \delta y) + V(x, y - \delta y) \\
= 4V(x, y) + (\delta x)^2 \left( \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} \right) + \ldots \\
\approx 4V(x, y), \tag{7.11}
\]

The second term in the second line was eliminated by using equation (7.10).

We map the coordinates of the lattice points to integers \((i, j)\) such that \(x_i = (i - 1)a\) and \(y_j = (j - 1)a\) where \(i, j = 1, \ldots, L\). By taking \(\delta x = \delta y = a\) so that \(x_i \pm \delta x = x_i \pm a = (i - 1 \pm 1)a = x_{i\pm1}\) and \(y_j \pm \delta y = y_j \pm a = (j - 1 \pm 1)a = y_{j\pm1}\), equation (7.11) becomes:
\[
V(i, j) = \frac{1}{4}(V(i - 1, j) + V(i + 1, j) + V(i, j - 1) + V(i, j + 1)). \tag{7.12}
\]

The equation above states that the potential at the position \((i, j)\) is the arithmetic mean of the potential of the nearest neighbors. We will describe an algorithm which belongs to the class of “successive overrelaxation methods” (SOR) whose basic steps are:

1. Set the size \(L\) of the square lattice.

2. Flag the sites that correspond to “conductors”, i.e. the sites where the potential remains fixed to the boundary conditions values.

3. Choose an initial trial function for \(V(x, y)\) on the vacuum sites. Of course it is not the solution we are looking for. A good choice will lead to fast convergence of the algorithm to the true solution. A bad choice may lead to slow convergence, no convergence or even convergence to the wrong solution. In our case the problem is easy and the simple choice \(V(x, y) = 0\) will do.

4. Sweep the lattice and enforce equation (7.12) on each visited vacuum site. This defines the new value of the potential at this site.

5. Sweep the lattice repeatedly until two successive sweeps result in a very small change in the function \(V(x, y)\).

A careful study of the above algorithm requires to test different criteria of “very small change” and test that different choices of the initial function \(V(x, y)\) result in the same solution.
We write a program that implements this algorithm in the case of a system which is the projection of two parallel conducting planes inside a grounded cubic box on the plane. The lattice is depicted in figure 7.6, where the black dots correspond to the conductors. All the points of the box have $V = 0$ and the two conductors are at constant potential $V_1$ and $V_2$ respectively. The user enters the values $V_1$ and $V_2$, the lattice size $L$ and the required accuracy interactively. The latter is determined by a small number $\epsilon$. The convergence criterion that we set is that the maximum difference between the values of the potential between two successive sweeps should be less than $\epsilon$.

The data structure is very simple. We use a real array $V(L,L)$ in order to store the values of the potential at each lattice site. A logical array $isConductor(L,L)$ flags each site as a “conductor site” ( = .TRUE.) or as a “vacuum site” ( = .FALSE.).

The main program reads in the data entered by the user and then calls three subroutines:

1. **initialize_lattice(V,isConductor,L,V1,V2):**
   The routine needs at its input the values of the potential $V_1$ and $V_2$ on the left and right plate respectively and the size of the lattice $L$. On exit it provides the initial values of the potential $V(L,L)$ and the flags $isConductor(L,L)$. The geometry of the setting is hard coded and the user needs to change this subroutine each time that she wants to study a different geometry.

2. **laplace(V,isConductor,L,epsilon):**
   This is the heart of the program. On entry we provide the initialized arrays $V(L,L)$ and $isConductor(L,L)$, the lattice size $L$, and the desired accuracy $epsilon$. On exit we obtain the final solution $V(L,L)$. This subroutine calculates the arithmetic mean of the potential of the nearest neighbors $V_{av}$ and the value $V(i,j)=V_{av}$ is changed immediately. The maximum change in the new value of the potential $V_{av}$ from the old one $V(i,j)$ is stored in the variable $error$. When $error$ becomes smaller than $epsilon$ we assume that convergence has been achieved.

3. **print_results(V,L):**
   This subroutine prints the potential $V(L,L)$ to the file data. Each line contains the integers $i, j$ and the value of the potential $V(i,j)$.

---

*A different choice would have been to store the value $V_{av}$ in a temporary array $V_{new}(i,j)$. After the sweep, the potential $V(i,j)=V_{new}(i,j)$ is changed to the new values. Which method do you expect to have better convergence properties? Try...*
We note that each time that the index $i$ changes, the subroutine prints an extra empty line. This is done so that the output can be read easily by the three dimensional plotting function `splot` of `gnuplot`.

The full program is listed below:

7.6 Results

The program in the previous section is written in the file LaplaceEq.f90. Compiling and running is done with the commands:

```fortran
! We change V only for non conductors:
if (.NOT. isConductor(i,j)) then
  Vav = ( V(i-1,j)+V(i+1,j)+V(i,j+1)+V(i,j-1) ) * 0.25d0
  dV = DABS(V(i,j)-Vav)
  if (error .LT. dV ) error = dV ! maximum error
  V(i,j) = Vav ! we immediately update V(i,j)
endif
enddo
icount = icount + 1
print *, icount, ' err = ', error
if ( error .LT. epsilon ) return ! return to main program
enddo
end subroutine laplace

! subroutine print_results
! Prints the array V(L,L) in file "data"
! The format of the output is appropriate for the splot function of gnuplot: Each time i changes an empty line is printed.
!
-- input:
! integer L: size of array V
! real(8) V(L,L): array to be printed
!
-- output:
! no output

subroutine print_results(V,L)
  implicit none
  integer :: L
  real(8), dimension(L,L) :: V
  integer :: i, j

  open(unit=11, file="data")
  do i=1,L
    do j=1,L
      write(11,*), i, j, V(i,j)
    enddo
    write(11,*),' empty line for gnuplot, separate isolines
  enddo
end subroutine print_results
```
In the example above, the program performs 112 sweeps until the error becomes $0.00958048937 < 0.01$. The results are stored in the file `data`. We can make a three dimensional plot of the function $V(i,j)$ with the `gnuplot` commands:

```
> gfortran LaplaceEq.f90 -o lf
> ./lf
Enter V1,V2:
100  -100
Enter epsilon:
0.01
Starting Laplace:
Grid Size = 31
Conductors set at V1= 100. V2= -100.
Relaxing with accuracy epsilon= 0.01
1 err= 33.3333333
2 err= 14.8148148
3 err= 9.87654321

......................................
110 err= 0.0106860904
111 err= 0.0101182476
112 err= 0.00958048937
```

The results are shown in figure 7.7

### 7.7 Poisson Equation

This section contains a short discussion of the case where the space is filled with a continuous static charge distribution given by the charge density function $\rho(\vec{r})$. In this case the Laplace equation becomes the Poisson equation:

$$\nabla^2 V = \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = -4\pi \rho(x, y, z) \quad (7.13)$$

The equation on the lattice becomes

$$V(i,j) = \frac{1}{4} (V(i-1,j) + V(i+1,j) + V(i,j-1) + V(i,j+1) + \bar{\rho}(i,j)) \quad (7.14)$$
Figure 7.7: The solution of the equation (7.10) computed by the program LaplaceEq.f90 for $L=31$, $V_1=100$, $V_2=-100$, $\epsilon=0.01$.

where

\[ \rho(i,j) = 4\pi a^2 \rho(i,j). \]

The program in the file PoissonEq.f90 solves equation (7.14) for a uniform charge distribution (figure 7.10), where we have set $a=1$. The reader is asked to reproduce this figure together with figures 7.8 and 7.9.

---

Since $Q = \int \rho dA \approx \sum_{i,j} \rho a^2 = (1/4\pi) \sum_{i,j} \rho$. Therefore $\sum_{i,j} \rho \approx 4\pi Q$. 

---
Figure 7.8: The solution of the equation (7.13) by the program in the file Poisson.f90 for $L = 51$, $V = 0$ on the boundary and the charge $4\pi Q = 1000$ all concentrated at one point.

```
print *, 'Enter 4*PI*Q: '
read *, Q
print *, 'Enter epsilon: '

subroutine laplace(V,isConductor,rho,L,epsilon)
! ************************************************************
implicit none
integer :: L
logical, dimension(L,L) :: isConductor
real(8), dimension(L,L) :: V,rho
real(8) :: epsilon
integer :: i,j,icount
```

real(8)    :: Vav,error,dV

icount = 0
do while (.TRUE.)
  error = 0.0D0
  do j=2,L-1
    do i=2,L-1
      !We change the voltage only for non conductors:
      if( .NOT. isConductor(i,j)) then
        Vav = (V(i-1,j)+V(i+1,j)+V(i,j+1)+V(i,j-1)+rho(i,j))&
             *0.25D0
        dV = DABS(V(i,j)-Vav)
        if(error .LT. dV ) error = dV !maximum error
        V(i,j) = Vav
      endif
    enddo
  enddo
  icount = icount + 1
  if( error .LT. epsilon ) exit
enddo
print *,icount,' err=',error
end subroutine laplace

In the bibliography the algorithm described above is called the Gauss–
Seidel method. In this method, the right hand side of equation (7.14)
uses the updated values of the potential in the calculation of $V(i,j)$ and
$V(i,j)$ is immediately updated. In contrast, the Jacobi method uses the
old values of the potential in the right hand side of (7.14) and the new
value computed is stored in order to be used in the next sweep. The
Gauss–Seidel method is superior to the Jacobi method as far as speed of
convergence is concerned. We can generalize Jacobi’s method by defining the residual \( R_{i,j} \) of equation (7.14)

\[
R_{i,j} = V(i + 1, j) + V(i - 1, j) + V(i, j + 1) + V(i, j - 1) - 4V(i, j) + \rho(i, j),
\]

which vanishes when \( V(i, j) \) is a solution of equation (7.14). Then, using \( R_{i,j} \), Jacobi’s method can be formulated as

\[
V^{(n+1)}(i, j) = V^{(n)}(i, j) + \frac{1}{4} R^{(n)}_{i,j},
\]

where the quantities with index \( (n) \) refer to the values of the potential during the \( n \)-th sweep. The successive overrelaxation (SOR) method is given by:

\[
V^{(n+1)}(i, j) = V^{(n)}(i, j) + \frac{\omega}{4} R^{(n)}_{i,j}.
\]

When \( \omega < 1 \) we have “underrelaxation” and we obtain slower convergence than the Jacobi method. When \( 1 < \omega < 2 \) we have “overrelaxation” and an appropriate choice of \( \omega \) can lead to an improvement compared to the Jacobi method. When \( \omega > 2 \) SOR diverges. Further study of the SOR methods is left as an exercise to the reader.
7.8 Problems

7.1 Reproduce the figures with the electric field lines and equipotential lines shown in section 7.2.

7.2 Take the charge distributions that you used in the previous problems, make all the charges to be positive and remake the figures of the field lines and the equipotential lines. Then repeat by taking half of the charges to be twice in magnitude than the others.

7.3 The program ELines.f90 gets stuck when you apply it on a charge distribution of four equal charges located at the vertices of a square. How can you correct this pathology?

7.4 Make the necessary changes to the program in the file ELines.f90 so that the number of field lines starting near a charge $q$ is proportional to $q$.

7.5 Improve the program in EPotential.f90 so that the equipotential lines are drawn with a density proportional to the magnitude of the electric field.

Hint:

(a) Write a subroutine that calculates the potential $V(x,y)$ at the point $(x,y)$.

(b) From each point charge draw a line in the radial direction and calculate the potential on points that are at small distance $\Delta l$ from each other.

(c) Calculate the maximum/minimum value of the potential $V_{\text{max}}/V_{\text{min}}$ and use them in order to choose the values of the potential on the equipotential lines that you plan to draw. If e.g. you choose to draw 5 equipotential lines, take $\delta V = (V_{\text{max}} - V_{\text{min}})/4$ and $V_i = V_{\text{min}} + i\delta V$ $i = 0,\ldots,4$.

(d) Repeat the second step. When the potential at a point takes approximately one of the values $V_i$ chosen in the previous step, draw an equipotential line from that point.

7.6 Compute the electric potential using the program in the file LaplaceEq.f90 for

(a) $L=31$, $V1=100$, $V2=100$

(b) $L=31$, $V1=100$, $V2=0$
7.7 Compute the electric potential using the program in the file LaplaceEq.f90 for
(a) $V_1=100, \ V_2=100$
(b) $V_1=100, \ V_2=100$
(c) $V_1=100, \ V_2=0$
for $L=31, 61, 121, 241, 501$ and construct the corresponding plot for $V(i,j)$. Vary epsilon=0.1, 0.01, 0.001, 0.0001, 0.00001, 0.000001. What is the dependence of the number of sweeps $N$ on epsilon? Make the plot of $N(\text{epsilon})$. Put the points and curves of $N(\text{epsilon})$ for all values of $L$ on the same plot.

7.8 Compute the electrostatic potential of a square conductor when the potential on each side is $V_1, \ V_2, \ V_3, \ V_4$. Repeat what you did in the previous problem for
(a) $V_1=10, \ V_2=5, \ V_3=10, \ V_4=5$
(b) $V_1=10, \ V_2=0, \ V_3=0, \ V_4=-10$
(c) $V_1=10, \ V_2=0, \ V_3=0, \ V_4=0$

7.9 Compute the electrostatic potential of a system of square conductors where the one is inside the other as shown in figure 7.11. The side of each conductor has $L_1, \ L_2$ sites respectively and the value of the potential is $V_1, V_2$ respectively. Take $L_2= L_1/5$ and repeat the steps in the previous problem for $V_1=10, \ V_2=-10$ and $L_1=25, \ 50, \ 100, \ 200$.

7.10 Perform a numerical computation of the capacitance $C = Q/V$ of the system of conductors of the previous problem when $V_1 = V, \ V_2 = -V$. In order to calculate the charge $Q$, compute the surface charge density $\sigma$ using the equation

$$\sigma = \frac{E_n}{4\pi},$$

where $E_n$ is the perpendicular component of the electric field on the surface. Use the approximation

$$E_n = -\frac{\delta V}{\delta r},$$
7.8. PROBLEMS

where $\delta V$ is the potential difference between a point on the conductor and its nearest neighbor. By integrating (i.e. summing) you can estimate the total charge on each conductor. If these are opposite and their absolute value is $Q$, then the capacitance can be calculated from the equation $C = Q/V$. Perform the calculation described above for $V = 10$ and $L_1 = 25, 75$.

7.11 In the system of the previous problem compute the function $Q(V)$. Verify that the capacitance is independent of $V$. Use $L_1 = 25, 50$, $V_1 = -V_2 = 1, 2, 5, 10, 15, 20, 25$.

7.12 Reproduce figures \[7.8, 7.9\] and \[7.10\]. Compare the result of the first case with the known solution of a point charge in empty space.

7.13 Introduce the lattice spacing $a$ in the corresponding equations in the program in the file PoissonEq.f90. Set the length of each side to be $l = 1$ and print the results in the file data as $(x_i, y_i, V(x_i, y_i))$ instead of $(i, j, V(i, j))$. Take $L = 51, 101, 151, 201, 251$ and plot $V(x, y)$ in the square $0 < x < 1$, $0 < y < 1$. Study the convergence of the solutions by plotting the section $V(x, 1/2)$ for each $L$.

7.14 Write a program that implements the SOR algorithm given by equa-
7.16 Write a program that implements the SOR algorithm given by equation (7.16) for the problem solved in LaplaceEq.f90. Compare the speed of convergence of SOR with that of the Gauss-Seidel method for $L = 51$, $\omega = 1.0, 0.9, 0.8, 0.6, 0.4, 0.2$. What happens when $\omega > 1$?

7.15 Write a program that implements the SOR algorithm given by equation (7.16) for the problem solved in PoissonEq.f90. Compare the speed of convergence of SOR with that of the Gauss-Seidel method for $L = 51$, $\omega = 1.0, 0.9, 0.8, 0.6, 0.4, 0.2$. What happens when $\omega > 1$?
Chapter 8

Diffusion Equation

8.1 Introduction

The diffusion equation is related to the study of random walks. Consider a particle moving on a line (one dimension) performing a random walk. The motion is stochastic and the kernel

\[ K(x, x_0; t), \]  

(8.1)

is interpreted as the probability density to observe the particle at position \( x \) at time \( t \) if the particle is at \( x_0 \) at \( t = 0 \). The equation that determines \( K(x, x_0; t) \) is

\[ \frac{\partial K(x, x_0; t)}{\partial t} = D \frac{\partial^2 K(x, x_0; t)}{\partial x^2}, \]  

(8.2)

which is the diffusion equation. The coefficient \( D \) depends on the details of the system that is studied. For example, for the Brownian motion of a dust particle in a fluid which moves under the influence of random collisions with the fluid particles, we have that \( D = kT/\gamma \), where \( T \) is the (absolute) temperature of the fluid, \( \gamma \) is the friction coefficient of the particle in the fluid and \( k \) is the Boltzmann constant.

Usually the initial conditions are chosen so that at \( t = 0 \) the particle is localized at one point \( x_0 \), i.e.

\[ K(x, x_0; 0) = \delta(x - x_0). \]  

(8.3)

\(^1\)For a spherical particle of radius \( R \) in a Newtonian liquid with viscosity \( \eta \) we have that \( \gamma = 6\pi\eta R \).

\(^2\) \( \delta(x - x_0) \) is the Dirac delta “function”. It can be defined from the requirement that for every function \( f(x) \) we have that \( \int_{-\infty}^{+\infty} f(x) \delta(x - x_0) \, dx = f(x_0) \). Obviously we also have that \( \int_{-\infty}^{+\infty} \delta(x - x_0) \, dx = 1 \). Intuitively one can think of it as a function that is almost zero everywhere except in an infinitesimal neighborhood of \( x_0 \).
CHAPTER 8. DIFFUSION EQUATION

The interpretation of \( K(x, x_0; t) \) as a probability density implies that for every \( t \) we should have that

\[
\int_{-\infty}^{+\infty} K(x, x_0; t) \, dx = 1. \tag{8.4}
\]

It is not obvious that this relation can be imposed for every instant of time. Even if \( K(x, x_0; t) \) is normalized so that (8.4) holds for \( t = 0 \), the time evolution of \( K(x, x_0; t) \) is governed by equation (8.2) which can spoil equation (8.4) at later times.

If we impose equation (8.4) at \( t = 0 \), then it will hold at all times if

\[
\frac{d}{dt} \int_{-\infty}^{+\infty} K(x, x_0; t) \, dx = 0. \tag{8.5}
\]

By taking into account that \( \frac{d}{dt} \int_{-\infty}^{+\infty} K(x, x_0; t) \, dx = \int_{-\infty}^{+\infty} \frac{\partial K(x, x_0; t)}{\partial t} \, dx \) and that \( \frac{\partial K(x, x_0; t)}{\partial t} = D \frac{\partial^2 K(x, x_0; t)}{\partial x^2} \) we obtain

\[
\frac{d}{dt} \int_{-\infty}^{+\infty} K(x, x_0; t) \, dx = D \int_{-\infty}^{+\infty} \left. \frac{\partial K(x, x_0; t)}{\partial x} \right|_{x \to +\infty} - D \left. \frac{\partial K(x, x_0; t)}{\partial x} \right|_{x \to -\infty}. \tag{8.6}
\]

The above equation tells us that for functions for which the right hand side vanishes, the normalization condition will be valid for all \( t > 0 \).

A careful analysis of equation (8.2) gives that the asymptotic behavior of \( K(x, x_0; t) \) for small times is

\[
K(x, x_0; t) \sim e^{-d(x-x_0)^2/4Dt} \sum_{i=0}^{\infty} a_i(x, x_0) t^i. \tag{8.7}
\]

This relation shows that diffusion is isotropic (the same in all directions) and that the probability of detecting the particle drops exponentially with the distance squared from the initial position of the particle. This relation cannot hold for all times, since for large enough times the probability of detecting the particle will be the same everywhere.\(^4\)

\(^4\)Alternatively, if \( K(x, x_0; t) \) is interpreted as e.g. the mass density of a drop of ink of mass \( m_{\text{ink}} \) inside a transparent liquid, we will have that \( \int_{-\infty}^{+\infty} K(x, x_0; t) \, dx = m_{\text{ink}} \) and \( K(x, x_0; 0) = m_{\text{ink}} \delta(x - x_0) \).

\(^\dagger\)Remember the analogy of an ink drop diffusing in a transparent liquid. After long enough time, the ink is homogeneously dissolved in the liquid.
8.2. HEAT CONDUCTION IN A THIN ROD

The return probability of the particle to its initial position is

\[ P_R(t) = K(x_0, x_0; t) \sim \frac{1}{t^{d/2}} \sum_{i=0}^{\infty} a_i(x_0, x_0) t^i. \] (8.8)

The above relation defines the spectral dimension \( d \) of space. \( d = 1 \) in our case.

The expectation value of the distance squared of the particle at time \( t \) is easily calculated:

\[ \langle r^2 \rangle = \langle (x - x_0)^2 \rangle(t) = \int_{-\infty}^{+\infty} (x - x_0)^2 K(x, x_0; t) \, dx \sim 2Dt. \] (8.9)

This equation is very important. It tells us that the random walk (Brownian motion) is not a classical motion but it can only be given a stochastic description: A classical particle moving with constant velocity \( v \) so that \( x - x_0 \sim vt \) results in \( r^2 \sim t^2 \).

In the following sections we take \( D = 1 \) and define

\[ u(x, t) \equiv K(x - x_0, x_0; t). \] (8.10)

8.2 Heat Conduction in a Thin Rod

Consider a thin rod of length \( L \) and let \( T(x, t) \) be the temperature distribution within the rod at time \( t \). The two ends of the rod are kept at constant temperature \( T(0, t) = T(L, t) = T_0 \). If the initial temperature distribution in the rod is \( T(x, 0) \), then the temperature distribution at all times is determined by the diffusion equation

\[ \frac{\partial T(x, t)}{\partial t} = \alpha \frac{\partial^2 T(x, t)}{\partial x^2}, \] (8.11)

where \( \alpha = k/(c_p \rho) \) is the thermal diffusivity, \( k \) is the thermal conductivity, \( \rho \) is the density and \( c_p \) is the specific heat of the rod.

Define

\[ u(x, t) = \frac{T(xL, \frac{L^2}{\alpha t}) - T_0}{T_0}, \] (8.12)

where \( x \in [0, 1] \). The function \( u(x, t) \), giving the fraction of the temperature difference to the temperature at the ends of the rod, is dimensionless and

\[ u(0, t) = u(1, t) = 0. \] (8.13)

---

\(^5\int_0^{\infty} r^ne^{-r^2/4Dt} = 2^n \Gamma\left(\frac{n+1}{2}\right)(Dt)^{-n/2}.\)

\(^6\)According to equation (8.2) this amounts to taking \( t \to Dt \).
These are called Dirichlet boundary conditions.\(^7\)

Equation (8.11) becomes

\[
\frac{\partial u(x, t)}{\partial t} = \frac{\partial^2 u(x, t)}{\partial x^2}
\]  

(8.14)

Equation (8.6) becomes

\[
\frac{d}{dt} \int_0^1 u(x, t) dx = \left. \frac{\partial u}{\partial x} \right|_{x=1} - \left. \frac{\partial u}{\partial x} \right|_{x=0}
\]

(8.15)

The relation above cannot be equal to zero at all times due to the boundary conditions (8.13). This can be easily understood with an example. Suppose that

\[
u(x, 0) = \sin(\pi x),
\]

(8.16)

then it is easy to confirm that the boundary conditions are satisfied and that the function

\[
u(x, t) = \sin(\pi x)e^{-\pi^2 t},
\]

(8.17)

is the solution to the diffusion equation. It is easy to see that

\[
\int_0^1 u(x, t) dx = \frac{2}{\pi}e^{-\pi^2 t}
\]

drops exponentially with time and that

\[
\frac{d}{dt} \int_0^1 u(x, t) dx = -2\pi e^{-\pi^2 t},
\]

which is in agreement with equations (8.15).

The exponential drop of the magnitude of \(u(x, t)\) is in agreement with the expectation that the rod will have constant temperature at long times, which will be equal to the temperature at its ends (\(\lim_{t \to +\infty} u(x, t) = 0\)).

### 8.3 Discretization

The numerical solution of equation (8.14) will be computed in the interval \(x \in [0, 1]\) for \(t \in [0, t_f]\). The problem will be defined on a two dimensional discrete lattice and the differential equation will be approximated by finite difference equations.

\(^7\)If the derivative \(\partial u/\partial x\) was given as a boundary condition instead, then we would have Neumann boundary conditions.
The lattice is defined by $N_x$ spatial points $x_i \in [0, 1]$

$$x_i = 0 + (i - 1)\Delta x \quad i = 1, \ldots, N_x,$$

(8.18)

where the $N_x - 1$ intervals have the same width

$$\Delta x = \frac{1 - 0}{N_x - 1},$$

(8.19)

and by the $N_t$ time points $t_j \in [0, t_f]$

$$t_j = 0 + (j - 1)\Delta t \quad j = 1, \ldots, N_t,$$

(8.20)

where the $N_t - 1$ time intervals have the same duration

$$\Delta t = \frac{t_f - 0}{N_t - 1}.$$

(8.21)

We note that the ends of the intervals correspond to

$$x_1 = 0, \quad x_{N_x} = 1, \quad t_1 = 0, \quad t_{N_t} = t_f.$$

(8.22)

The function $u(x, t)$ is approximated by its values on the $N_x \times N_t$ lattice

$$u_{i,j} \equiv u(x_i, t_j).$$

(8.23)

The derivatives are replaced by the finite differences

$$\frac{\partial u(x, t)}{\partial t} \approx \frac{u(x_i, t_j + \Delta t) - u(x_i, t_j)}{\Delta t} \equiv \frac{1}{\Delta t} (u_{i,j+1} - u_{i,j}),$$

(8.24)

$$\frac{\partial^2 u(x, t)}{\partial x^2} \approx \frac{u(x_i + \Delta x, t_j) - 2u(x_i, t_j) + u(x_i - \Delta x, t_j)}{(\Delta x)^2}
\equiv \frac{1}{(\Delta x)^2} (u_{i+1,j} - 2u_{i,j} + u_{i-1,j}).$$

(8.25)

By equating both sides of the above relations according to (8.14), we obtain the dynamic evolution of $u_{i,j}$ in time

$$u_{i,j+1} = u_{i,j} + \frac{\Delta t}{(\Delta x)^2} (u_{i+1,j} - 2u_{i,j} + u_{i-1,j}).$$

(8.26)

This is a one step iterative relation in time. This is very convenient, because one does not need to store the values $u_{i,j}$ for all $j$ in the computer memory.
The second term (the “second derivative”) in (8.26) contains only the nearest neighbors \( u_{i\pm 1,j} \) of the lattice point \( u_{i,j} \) at a given time slice \( t_j \). Therefore it can be used for all \( i = 2, \ldots, N_x - 1 \). The relations (8.26) are not needed for the points \( i = 1 \) and \( i = N_x \) since the values \( u_{1,j} = u_{N_x,j} = 0 \) are kept constant.

The parameter
\[
\frac{\Delta t}{(\Delta x)^2}
\]
(8.27)
determines the time evolution in the algorithm. It is called the Courant parameter and in order to have a time evolution without instabilities it is necessary to have
\[
\frac{\Delta t}{(\Delta x)^2} < \frac{1}{2}.
\]
(8.28)
This condition will be checked in our analysis empirically.

---

**Figure 8.1:** The function \( u(x,t) \) for \( N_x=10, \ N_t=100, \ tf= 0.4 \).

---

### 8.4 The Program

The fact that equation (8.26) is a one time step iterative relation, leads to a substantial simplification of the structure of the program. Because of this, at each time step, it is sufficient to store the values of the second term (the “second derivative”) in one array. This array will be used in order
to update the values of \( u_{i,j} \). Therefore we will define only two arrays \( u_i \), \( i = 1, \ldots, N_x \) and \((\partial^2 u/\partial x^2)_i, i = 1, \ldots, N_x \) which store the values of \( u_{i,j} \) and \( \Delta t/(\Delta x)^2(u_{i+1,j} - 2u_{i,j} + u_{i-1,j}) \) at time \( t_j \) respectively. In the program listed below, the names of these arrays are \( u(P) \) and \( d2udx2(P) \).

The data is stored in the array positions \( u(1) \ldots u(N_x) \) and \( d2udx2(1) \ldots d2udx2(N_x) \) and the parameter \( P \) is taken large enough so that \( N_x \) is always smaller than \( P \).

The user enters the \( N_x = Nx, N_t = Nt \) and \( t_f = tf \) interactively. The values of \( \Delta x, \Delta t \) and \( \Delta t/\Delta x^2 = \text{courant} \) are calculated during the initialization.

On exit, we obtain the results in the file \( d.dat \) which contains \((t_j, x_i, u_{i,j})\) in three columns. When a time slice is printed, the program prints an empty line so that the output is easily read by the three dimensional plotting function \( \text{splot} \) of gnuplot.

The program is in the file \( \text{diffusion.f90} \) and is listed below:

```fortran

\text{end program diffusion_1d}
8.5 Results

The compilation and running of the program can be done with the commands:

```
> gfortran diffusion.f90 -o d
> echo "10 100 0.4" | ./d
```

The input to the program ./d is read from the stdin and it is given by the stdout of the command echo through a pipe, as shown in the second line in the listing above. The lines that follow are the standard output stdout of the program.

The three dimensional plot of the function \( u(x,t) \) can be made with the gnuplot commands:

```
gnuplot> set pm3d
gnuplot> set hidden3d
gnuplot> splot "d.dat" with lines
gnuplot> unset pm3d
```

In order to make the plot of \( u(x,t) \) for a fixed value of \( t \) we first note that an empty line in the file d.dat marks a change in time. The following awk program counts the empty lines of d.dat and prints only the lines when the number of empty lines that have been encountered so far is equal to 3. The counter \( n=0, 1, \ldots, Nt-1 \) determines the value of \( t_j = t_{n-1} \). We save the results in the file tj which can be plotted with gnuplot. We repeat as many times as we wish:

```
> awk 'NF<3{n++}n==3 {print}' d.dat > tj
```

The above task can be completed without creating the intermediate file tj by using the awk filter within gnuplot. For example, the commands

```
gnuplot> ! echo "10 800 2" | ./d
```

The lines that follow are the standard output stdout of the program.
Figure 8.2: The function $u(x, t)$ for $N_x=10$, $N_t=800$, $t_f=2$ for different values of the time $t_j$. We take $j = 4, 7, 11, 21, 31, 51, 101$ and observe that the function $u(x, t)$ decreases then $j$ increases.

It is instructive to compare the results with the known solution $u(x, t) = \sin(\pi x)e^{-\pi^2 t}$. We compute the relative error

$$\frac{u_{i,j} - u(x_i, t_j)}{u_{i,j}},$$

which can be done within gnuplot with the commands:

```
gnuplot> du(x,y,z) = (z - sin(pi*x)*exp(-pi*pi*y))/z
gnuplot> plot "<awk 'NF<3{n++}n==2' d.dat" u 2:(du($2,$1,$3))
gnuplot> plot "<awk 'NF<3{n++}n==6' d.dat" u 2:(du($2,$1,$3))
gnuplot> plot "<awk 'NF<3{n++}n==20' d.dat" u 2:(du($2,$1,$3))
gnuplot> plot "<awk 'NF<3{n++}n==200' d.dat" u 2:(du($2,$1,$3))
gnuplot> plot "<awk 'NF<3{n++}n==600' d.dat" u 2:(du($2,$1,$3))
gnuplot> plot "<awk 'NF<3{n++}n==780' d.dat" u 2:(du($2,$1,$3))
```

The results can be seen in figure 8.3.
8.6 Diffusion on the Circle

In order to study the kernel $K(x, x_0; t)$ for the diffusion, or random walk, problem, we should impose the normalization condition (8.4) for all times. In the case of the function $u(x, t)$ defined for $x \in [0, 1]$ the relation becomes

$$
\int_0^1 u(x, t) \, dx = 1.
$$

In order to maintain this relation at all times, it is necessary that the right hand side of equation (8.15) is equal to 0. One way to impose this condition is to study the diffusion problem on the circle. If we parametrize the circle using the variable $x \in [0, 1]$, then the points $x = 0$ and $x = 1$ are identified and we obtain

$$
u(0, t) = u(1, t), \quad \frac{\partial u(0, t)}{\partial x} = \frac{\partial u(1, t)}{\partial x}.
$$

The second relation in the above equations makes the right hand side of equation (8.15) to vanish. Therefore if $\int_0^1 u(x, 0) \, dx = 1$, we obtain $\int_0^1 u(x, t) \, dx = 1, \forall t > 0$.

Using the above assumptions, the discretization of the differential equation is done exactly as in the problem of heat conduction. Instead
of keeping the values \( u(0, t) = u(1, t) = 0 \), we apply equation (8.26) also for the points \( x_1, x_{N_x} \). In order to take into account the cyclic topology we take

\[
\begin{align*}
    u_{1,j+1} &= u_{1,j} + \frac{\Delta t}{(\Delta x)^2} (u_{2,j} - 2u_{1,j} + u_{N_x,j}) , \\
    u_{N_x,j+1} &= u_{i,j} + \frac{\Delta t}{(\Delta x)^2} (u_{1,j} - 2u_{N_x,j} + u_{N_x-1,j}) ,
\end{align*}
\]

since the neighbor to the right of the point \( x_{N_x} \) is the point \( x_1 \) and the neighbor to the left of the point \( x_1 \) is the point \( x_{N_x} \). For the rest of the points \( i = 2, \ldots, N_x - 1 \) equation (8.26) is applied normally.

The program that implements the problem described above can be found in the file diffusionS1.f90. The boundary conditions (8.30) are enforced in the lines

```fortran
    nnr = i+1
    if (nnr.gt. Nx) nnr = 1
    nnl = i-1
    if (nnl.lt. 1 ) nnl = Nx
    d2ux2(i) = courant* (u(nnrl) - 2.0D0*u(i) + u(nnrl))
```

The initial conditions at \( t = 0 \) are chosen so that the particle is located at \( x_{N_x}/2 \). For each instant of time we perform measurements in order to verify the equations (8.7) and (8.9) and the fact that \( \lim_{t \to +\infty} u(x,t) = \text{const.} \)

The variable \( \text{prob} = \sum_{i=1}^{N_x} u_{i,j} \) and we should check that its value is conserved and is always equal to 1.

The variable \( r^2 = \sum_{i=1}^{N_x} (x_i - x_{N_x}/2)^2 u_{i,j} \) is a discrete estimator of the expectation value of the distance squared from the initial position. For small enough times it should follow the law given by equation (8.9).

These variables are written to the file e.dat together with the values \( u_{N_x/2,j} \), \( u_{N_x/4,j} \) and \( u_{1,j} \). The latter are measured in order to check if for large enough times they obtain the same constant value according to the expectation \( \lim_{t \to +\infty} u(x,t) = \text{const.} \).

The full code is listed below:

```fortran
! 1-dimensional Diffusion Equation with
! periodic boundary conditions u(0,t)=u(1,t)
! 0<= x <= 1 and 0<= t <= tf
!
! We set initial condition u(x,t=0) that satisfies
```

8.7 Analysis

For each moment of time, the program writes the following quantities to the file e.dat:

\[ U_j = \sum_{i=1}^{N_x} u_{i,j} \]  \hspace{1cm} (8.33)

which is an estimator of (8.29) and we expect to obtain \( U_j = 1 \) for all \( j \),

\[ \langle r^2 \rangle_j = \sum_{i=1}^{N_x} u_{i,j} (x_i - x_{N_x/2})^2 \]  \hspace{1cm} (8.34)

which is an estimator of (8.9) for which we expect to obtain

\[ \langle r^2 \rangle_j \sim 2t_j , \]  \hspace{1cm} (8.35)

for small times as well as the values of \( u_{N_x/2,j}, u_{N_x/4,j}, u_{1,j} \).
The values of $t_j$, $U_j$, $(r^2)_j$, $u_{N_x/2,j}$, $u_{N_x/4,j}$, $u_{1,j}$ are found in columns 2, 3, 4, 5, 6 and 7 respectively of the file e.dat. The gnuplot commands

```
$gnuplot> ! gfortran diffusionS1.f90 -o d
$gnuplot> ! echo "10 100 0.4" | ./d
```
compile and run the program within gnuplot. They set $N_x = 10$, $N_t = 100$, $t_f = 0.4$, $\Delta x \approx 0.111$, $\Delta t \approx 4.0404$, $\Delta t/\Delta x^2 \approx 0.327$. The gnuplot commands

```
$gnuplot> plot "e.dat" u 2:5 w l
$gnuplot> replot "e.dat" u 2:6 w l
$gnuplot> replot "e.dat" u 2:7 w l
```
construct the plot in figure 8.4. We observe that for large times we obtain uniform diffusion.

The relation $U_j = 1$ can be easily confirmed by inspecting the values recorded in the file e.dat.

The asymptotic relation $(r^2)_j \sim 2t_j$ can be confirmed with the commands

```
$gnuplot> plot "e.dat" u 2:5 w l
$gnuplot> replot "e.dat" u 2:6 w l
$gnuplot> replot "e.dat" u 2:7 w l
```
Figure 8.5: The expectation value $\langle r^2 \rangle_j$ as a function of $t_j$ for $N_x = 10$, $N_t = 100$, $t_f = 0.4$. For small values of $t_j$ we obtain $\langle r^2 \rangle_j \approx 2t_j$. The solid line is the straight line $2t$.

\begin{verbatim}
gnuplot> plot [:][:0.11] "e.dat" u 2:4*2*x
\end{verbatim}

which construct the plot in figure 8.5.

Finally we make a plot of the function $u(x,t)$ with the commands

\begin{verbatim}
gnuplot> ! echo "10 100 0.16" | ./d
gnuplot> set pm3d
 gnuplot> splot [0:0.16][0:1][0: 1] "d.dat" w l
gnuplot> splot [0:0.16][0:1][0:2] "d.dat" w l
\end{verbatim}

and the result is shown in figure 8.6.
Figure 8.6: The function $u(x, t)$ for $N_x = 10$, $N_t = 100$, $t_f = 0.16$. The second plot differs only in the scale of the $z$ axis so that we can easily see the details of the diffusion away from the point $x_0 \equiv x_{N_x/2} = x_5$. 
CHAPTER 8. DIFFUSION EQUATION

8.8 Problems

8.1 Reproduce the results in figure 8.3.

8.2 The temperature distribution \( u(x, t) \) in a thin rod satisfies equation (8.14) together with the boundary conditions (8.13) at the ends \( x = 0, 1 \). The initial temperature distribution at \( t = 0 \) is given by the function

\[
u(x, 0) = \begin{cases} 0.5 & x \in [x_1, x_2] \\ 0.3 & x \notin [x_1, x_2] \end{cases},
\]

where \( x_1 = 0.25 \) and \( x_2 = 0.75 \).

(a) Calculate the temperature distribution \( u(x, t_f) \) for \( t_f = 0.0001, \ 0.001, 0.01, 0.05 \). Take \( N_x = 100 \) and \( N_t = 1000 \). Do the same for \( t_f = 0.1 \) by choosing appropriate \( N_x \) and keeping \( N_t = 1000 \). Plot the functions \( u(x, t_f) \) in the same plot.

(b) Calculate the maximum value of the temperature graphically for \( t_f = 0.0001, 0.001, 0.01, 0.05, 0.1, 0.15, 0.25 \). Take \( N_x = 100 \) and choose an appropriate value for the corresponding \( N_t \).

(c) Calculate the time at which the temperature of the rod becomes everywhere less than 0.1.

Hint: Make your program print only the final temperature distribution \( u(x, t_f) \).

8.3 The temperature distribution \( u(x, t) \) in a thin rod satisfies the equation

\[
\frac{\partial u}{\partial t} = \alpha \frac{\partial^2 u}{\partial x^2}.
\]

The temperature at the ends of the rod is \( u(0, t) = u(1, t) = 0 \), and when \( t = 0 \)

\[
u(x, 0) = \begin{cases} 0.5 \left[ 1 - \cos \left( \frac{2\pi x}{b} \right) \right] & 0 \leq x < b \\ 0 & b \leq x \leq 1 \end{cases}.
\]

(a) Calculate the temperature distribution \( u(x, t_f) \) for \( \alpha = 0.5, b = 0.09 \) and for \( t_f = 0.0001, 0.001, 0.01 \), by taking \( N_x = 300, N_t = 1000 \). Do the same for \( t_f = 0.05 \) by choosing appropriate \( N_x \). Plot the functions \( u(x, t_f) \) in the same plot.

(b) Using the same parameters, calculate the time evolution of the values of the temperature distribution at the points \( x_1 = 0.05, x_2 = 0.50 \) and \( x_3 = 0.95 \) for \( 0 \leq t \leq 0.05 \). Plot the functions \( u(x_{1,2,3}, t) \) in the same plot.
8.8. **PROBLEMS**

(c) Calculate the temperature distribution \(u(x, t_f)\) for \(b = 0.09\) and \(\alpha = 5, 2, 1\) for \(t_f = 0.001\). Plot the functions \(u(x, t_f)\) in the same plot. Comment on the effect of the parameter \(\alpha\) on your results.

8.4 The temperature distribution \(u(x, t)\) in a thin rod of length \(L\) satisfies equation

\[
\frac{\partial u}{\partial t} = D(x) \frac{\partial^2 u}{\partial x^2} - \frac{4}{L} D(x) \frac{\partial u}{\partial x},
\]

where \(D(x) = ae^{-4x/L}\) is the \(x\)-dependent thermal diffusivity. The temperature of the rod at its ends is such that \(u(0, t) = u(L, t) = 0\), and at time \(t = 0\), the temperature distribution is

\[u(x, 0) = Ce^{-(x-L/2)^2/\sigma^2}.
\]

(a) Write a program where the user enters the parameters \(L, a, C, \sigma, N_x, N_t\) and \(t_f\) interactively. On exit, the program calculates \(u(x, t_f)\) and writes the points \((x_i, u(x_i, t_f))\) in two columns to a file \(d.dat\).

(b) Run the program for \(L = 4, a = 0.2, C = 1, \sigma = 1/2, N_x = 400, N_t = 20000\) and calculate \(u(x, t_f)\) for \(t_f = 0.05, 1.0, 5.0\). Plot the functions \(u(x, t_f)\) in the same plot.

(c) Using the same parameters, calculate the time evolution of the temperature distribution at the points \(x_1 = 1\) and \(x_2 = 2\) for \(0 \leq t \leq 5\). Plot the functions \(u(x_1, x_2, t)\) in the same plot.

8.5 Reproduce the results shown in figures 8.4 and 8.5.
Chapter 9

The Anharmonic Oscillator

In this chapter we will use matrix methods in order to compute the quantum mechanical energy spectrum of the anharmonic oscillator. This problem cannot be solved exactly and one has to resort to perturbative or other approximation methods. We will approach this problem numerically by representing the Hamiltonian $H$ as a real symmetric matrix in an appropriately chosen basis of the Hilbert space $\mathcal{H}$ of quantum mechanical states. The energy spectrum is obtained from the eigenvalues of this matrix and the numerical problem reduces to that of the diagonalization of a real symmetric matrix. Since the Hamiltonian is represented in $\mathcal{H}$ by an infinite size matrix, we have to restrict ourselves to a finite dimensional subspace $\mathcal{H}_N$ of dimension $N$. In this space the Hamiltonian is represented by an $N \times N$ real symmetric matrix. The eigenvalues of this matrix will be calculated numerically using standard methods and the energy eigenvalues will be obtained in the $N \to \infty$ limit.

For the calculation of the eigenvalues we will use software that is found in the well known library Lapack which contains high quality, freely available, linear algebra software. Part of the goals of this chapter is to show to the reader how to link her programs with software libraries. In order to solve the same problem using Mathematica or Matlab see [40] and [41] respectively.

9.1 Introduction

The Hamiltonian of the harmonic oscillator is given by

$$H_0 = \frac{p^2}{2m} + \frac{1}{2}m\omega^2 x^2.$$  \hfill (9.1)
Define the position and momentum scales \( x_0 = \sqrt{\hbar/(m\omega)} \), \( p_0 = \sqrt{\hbar m\omega} \) so that we can express the above equation using dimensionless terms:

\[
\frac{H_0}{\hbar\omega} = \frac{1}{2} \left( \frac{p}{p_0} \right)^2 + \frac{1}{2} \left( \frac{x}{x_0} \right)^2 .
\]  

(9.2)

If we take the units of energy, distance and momentum to be \( \hbar\omega \), \( x_0 \) and \( p_0 \), then we obtain

\[
H_0 = \frac{1}{2} p^2 + \frac{1}{2} x^2 ,
\]  

(9.3)

where \( H_0 \), \( p \) and \( x \) are now dimensionless. The operator \( H_0 \) can be diagonalized with the help of the creation and annihilation operators \( a \) and \( a^\dagger \), defined by the relations:

\[
x = \frac{1}{\sqrt{2}} (a^\dagger + a) \quad p = \frac{i}{\sqrt{2}} (a^\dagger - a) ,
\]  

(9.4)

or

\[
a = \frac{1}{\sqrt{2}} (x + ip) \quad a^\dagger = \frac{1}{\sqrt{2}} (x - ip) ,
\]  

(9.5)

which obey the commutation relation

\[
[a, a^\dagger] = 1 ,
\]  

(9.6)

which leads to

\[
H_0 = a^\dagger a + \frac{1}{2} .
\]  

(9.7)

The eigenstates \( |n\rangle \), \( n = 0, 1, 2, \ldots \) of \( H_0 \) span the Hilbert space of states \( \mathcal{H} \) and satisfy the relations

\[
a^\dagger |n\rangle = \sqrt{n+1} |n+1\rangle \quad a |n\rangle = \sqrt{n} |n-1\rangle \quad a |0\rangle = 0 ,
\]  

(9.8)

therefore

\[
a^\dagger a |n\rangle = n |n\rangle ,
\]  

(9.9)

and

\[
H_0 |n\rangle = E_n |n\rangle , \quad E_n = n + \frac{1}{2} .
\]  

(9.10)

The position representation of the eigenstates \( |n\rangle \) is given by the wavefunctions:

\[
\psi_n(x) = \langle x |n\rangle = \frac{1}{\sqrt{2^n n! \sqrt{\pi}}} e^{-x^2/2} H_n(x) ,
\]  

(9.11)

where \( H_n(x) \) are the Hermite polynomials.
9.2. CALCULATION OF THE EIGENVALUES OF $H_{NM}(\lambda)$

From equations (9.4) and (9.8) we obtain

$$x_{nm} = \langle n | x | m \rangle = \frac{1}{\sqrt{2}} \sqrt{m + 1} \delta_{n,m+1} + \frac{1}{\sqrt{2}} \sqrt{m} \delta_{n,m-1} \quad (9.12)$$

$$p_{nm} = \langle n | p | m \rangle = \frac{i}{\sqrt{2}} \sqrt{m + 1} \delta_{n,m+1} - \frac{i}{\sqrt{2}} \sqrt{m} \delta_{n,m-1} \quad (9.13)$$

From the above equations we can easily calculate the Hamiltonian of the \textit{anharmonic} oscillator

$$H(\lambda) = H_0 + \lambda x^4. \quad (9.15)$$

The matrix elements of $H$ in this representation are:

$$H_{nm}(\lambda) \equiv \langle n | H(\lambda) | m \rangle = \langle n | H_0 | m \rangle + \lambda \langle n | x^4 | m \rangle \quad (9.16)$$

$$= (n + \frac{1}{2}) \delta_{n,m} + \lambda (x^4)_{nm} \quad (9.17)$$

where $(x^4)_{nm}$ can be calculated from equation (9.12):

$$(x^4)_{nm} = \sum_{i_1,i_2,i_3=0}^{\infty} x_{ni_1} x_{i_1i_2} x_{i_2i_3} x_{i_3m}. \quad (9.18)$$

This relation computes the matrix elements of the matrix $x^4$ from the matrix product of $x$ with itself.

The problem of the calculation of the energy spectrum has now been reduced to the problem of calculating the eigenvalues of the matrix $H_{nm}$.

9.2 Calculation of the Eigenvalues of $H_{nm}(\lambda)$

We start by choosing the dimension $N$ of the subspace $H_N$ of the Hilbert space $H$. We will restrict ourselves to states within this subspace and we will use the $N$ dimensional representation matrices of $x$, $H_0$ and $H(\lambda)$ in $H_N$. For example, when $N = 4$ we obtain

$$x = \begin{pmatrix} 0 & \frac{1}{\sqrt{2}} & 0 & 0 \\ \frac{1}{\sqrt{2}} & 0 & 1 & 0 \\ 0 & 1 & 0 & \sqrt{3} \\ 0 & 0 & \sqrt{3} & 0 \end{pmatrix} \quad (9.19)$$
CHAPTER 9. THE ANHARMONIC OSCILLATOR

\[ H_0 = \begin{pmatrix} \frac{1}{2} & 0 & 0 & 0 \\ 0 & \frac{3}{2} & 0 & 0 \\ 0 & 0 & \frac{5}{2} & 0 \\ 0 & 0 & 0 & \frac{7}{2} \end{pmatrix} \]  \hspace{1cm} (9.20)

\[ H(\lambda) = \begin{pmatrix} \frac{1}{2} + \frac{3\lambda}{4} & 0 & \frac{3\lambda}{\sqrt{2}} & 0 \\ 0 & \frac{3}{2} + \frac{15\lambda}{4} & 0 & 3\sqrt{\frac{3}{2}\lambda} \\ \frac{3\lambda}{\sqrt{2}} & 0 & \frac{5}{2} + \frac{27\lambda}{4} & 0 \\ 0 & 3\sqrt{\frac{3}{2}\lambda} & 0 & \frac{7}{2} + \frac{15\lambda}{4} \end{pmatrix} \]  \hspace{1cm} (9.21)

Our goal is to write a program that calculates the eigenvalues \( E_n(N, \lambda) \) of the \( N \times N \) matrix \( H_{nm}(\lambda) \). Instead of reinventing the wheel, we will use ready made routines that calculate eigenvalues and eigenvectors of matrices found in the Lapack library. This library can be found in the high quality numerical software repository Netlib and more specifically at [http://www.netlib.org/lapack/](http://www.netlib.org/lapack/). Documentation can be found at [http://www.netlib.org/lapack/lug/](http://www.netlib.org/lapack/lug/), but it is also easily accessible online by using Google search or by using the man pages.

As inexperienced users we will first look for driver routines that perform a diagonalization process. Since our task is to diagonalize a real symmetric matrix, we pick the subroutine DSYEV (D = double precision, SY = symmetric, EV = eigenvalues with optional eigenvectors). If the documentation of the library is installed in our system, we may use the Linux man pages for accessing it.

\>$\text{man dsyev}$

From this page we learn how to use this subroutine:

```
SUBROUTINE DSYEV( JOBZ, UPLO, N, A, LDA, W, WORK, LWORK, INFO )
CHARACTER JOBZ, UPLO
INTEGER INFO, LDA, LWORK, N
DOUBLE PRECISION A( LDA, * ), W( * ), WORK( * )

ARGUMENTS
JOBZ (input) CHARACTER
```
9.2. CALCULATION OF THE EIGENVALUES OF $H_{NM}(\lambda)$

$= 'N'$: Compute eigenvalues only;
$= 'V'$: Compute eigenvalues and eigenvectors.

**UPLO** (input) CHARACTER*1
$= 'U'$: Upper triangle of $A$ is stored;
$= 'L'$: Lower triangle of $A$ is stored.

**N** (input) INTEGER
The order of the matrix $A$. $N \geq 0$.

**A** (input/output) DOUBLE PRECISION array,
dimension (LDA, N)
On entry, the symmetric matrix $A$. If UPLO = 'U', the
leading $N$-by-$N$ upper triangular part of $A$ contains the
upper triangular part of the matrix $A$. If UPLO = 'L', the
leading $N$-by-$N$ lower triangular part of $A$ contains
the lower triangular part of the matrix $A$. On exit, if
JOBZ = 'V', then if INFO = 0, $A$ contains
the orthonormal eigenvectors of the matrix $A$. If
JOBZ = 'N', then on exit the lower triangle (if UPLO='L')
or the upper triangle (if UPLO='U') of $A$, including the
diagonal, is destroyed.

**LDA** (input) INTEGER
The leading dimension of the array $A$. LDA $\geq \max(1, N)$.

**W** (output) DOUBLE PRECISION array, dimension (N)
If INFO = 0, the eigenvalues in ascending order.

**WORK** (workspace/output) DOUBLE PRECISION array, dimension
(LWORK).
On exit, if INFO = 0, WORK(1) returns the optimal LWORK.

**LWORK** (input) INTEGER
The length of the array WORK. LWORK $\geq \max(1, 3*N - 1)$.
For optimal efficiency, LWORK $\geq (\text{NB}+2)*N$, where NB is
the blocksize for DSYTRD returned by ILAENV.

If LWORK $= -1$, then a workspace query is assumed; the
routine only calculates the optimal size of the WORK
array, returns this value as the first entry of the
WORK array, and no error message related to LWORK is
issued by XERBLA.

**INFO** (output) INTEGER
$= 0$: successful exit
$< 0$: if INFO $= -i$, the $i$-th argument had an illegal value
> 0: if INFO = i, the algorithm failed to converge; ←
  i
off-diagonal elements of an intermediate tridiagonal
form did not converge to zero.

These originally cryptic pages contain all the necessary information and
the reader should familiarize herself with its format. For a quick and
dirty use of the routine, all we need to know is the types and usage of its
arguments. These are classified as “input”, “output” and “working space”
variables (some are in more than one classes). Input is the necessary data
that the routine needs in order to perform the computation. Output is
where the results of the computation are stored. And working space
is the memory provided by the user to the routine in order to store
intermediate results.

From the information above we learn that the matrix to be diagonal-
ized is \( A \) which is a rectangular matrix with the number of its rows and
columns \( \leq N \). The number of rows LDA (LDA= “leading dimension of
\( A \)”) can be larger than \( N \) is which case DSYEV will diagonalize the upper
left \( N \times N \) part of the matrix\(^5\). In our program we define a large matrix
\( A(LDA,LDA) \) and diagonalize a smaller submatrix \( A(N,N) \). This way we
can study many values of \( N \) using the same matrix. The subroutine can
be used in two ways:

- If JOBZ='N', it calculates only the eigenvalues of the matrix \( A(N,N) \)
and stores them in the array \( W(N) \), sorted in ascending order. We
have to be careful because, upon return, the routine destroys the
upper (UPLO='U') or lower (UPLO='L') triangular part of \( A \). Since
\( A \) is symmetric, only this part is needed by DSYEV. If we need to
reuse the matrix \( A \), we have to make a backup copy before the call
to DSYEV.

- If JOBZ='V', it calculates both the eigenvalues and the eigenvectors
of the matrix \( A(N,N) \). The eigenvalues are stored in the array \( W(N) \)
as before, whereas the corresponding eigenvectors in the columns
of the matrix \( A(N,N) \). In order to use the eigenvectors, we can use
a statement like \( v = A(1:N,j) \) where the array \( v(N) \) stores the
components of the \( j \)-th eigenvector of the matrix corresponding to
the eigenvalue \( \lambda_j \). The eigenvectors are normalized to unity, i.e.
\( \sum_{i=1}^{N} v(i) \ast v(i) = 1 \). The matrix \( A(N,N) \) is destroyed after the call

\(^5\)The number LDA is necessary because the matrix element \( A(i,j) \) is found after
\( i+(LDA-1)\ast j \) memory positions from \( A(1,1) \).
9.2. \textit{Calculation of the Eigenvalues of }$H_{NM}(\lambda)$

...to DSYEV and if we need it we have to make a backup copy before the call.

The reader should also familiarize herself with the use of the workspace array \texttt{WORK}. This is memory space given to the routine for all its intermediate calculations. Determining the size of this array needs some care. This is given by \texttt{LWORK} and if performance is an issue the reader should read the documentation carefully for its optimal determination. We will make the simple choice \texttt{LWORK}=3*LDA-1. The variable \texttt{INFO} is used as a flag which informs the user whether the calculation was successful, in which case its value is set to 0. In our case, if \texttt{INFO} takes a non zero value, the program will abort the calculation.

Before using the program in a complicated calculation, it is necessary to test its use in a simple, easily controlled problem. We will familiarize ourselves with the use of DSYEV by writing the following program:

```fortran
program test_evs
  implicit none
  integer, parameter :: P = 100 ! P= LDA
  integer :: LWORK = 3*P-1
  real(8) :: A(P,P), W(P), WORK(LWORK)
  integer :: N ! DSYEV diagonalizes A(N,N)
  integer :: i, j
  integer :: LDA, INFO
  character(1) :: JOBZ, UPLO

  ! Define the **symmetric** matrix to be diagonalized
  ! The subroutine uses the upper triangular part (\texttt{UPLO}='U')
  ! therefore the lower triangular part needs not to be defined
  N=4
  A(1,1)=-7.7;
  A(1,2)= 2.1; A(2,2) = 8.3;
  A(1,3)=-3.7; A(2,3)=-16.; A(3,3)=-12.
  A(1,4) = 4.4; A(2,4) = 4.6; A(3,4)=-1.04; A(4,4)=-3.7
  ! We print the matrix A before calling DSYEV since it is
  ! destroyed after the call.
  do i=1,N
    do j=i,N
      print *, 'A(', i, ', ', j, ')=', A(i,j)
    enddo
  enddo

  ! We ask for eigenvalues AND eigenvectors (\texttt{JOBZ}='V')
  JOBZ='V'; UPLO='U'
  print *, 'COMPUTING WITH DSYEV:
  LDA=P ! notice that LDA-> P>N !!
  call DSYEV(JOBZ, UPLO, N, A, LDA, W, WORK, LWORK, INFO)
  print *, 'DSYEV: DONE. CHECKING NOW:
```

CHAPTER 9. THE ANHARMONIC OSCILLATOR

If INFO is nonzero, then there is an error:

```fortran
if(INFO .ne. 0) then
  print *, 'DSYEV FAILED. INFO= ',INFO
  stop
endif
```

Print results: W(I) has the eigenvalues:

```fortran
print *, 'DSYEV: DONE.'
print *, 'EIGENVALUES OF MATRIX:
do i=1,N
  print *, 'LAMBDA(',i,')=',W(i)
enddo
```

Eigenvectors are stored in the columns of A:

```fortran
print *, 'EIGENVECTORS OF MATRIX
do J=1,N
  print *, 'EIGENVECTOR ',j,' FOR EIGENVALUE ',W(j)
  do i=1,N
    print *, 'V_',j,'(',',i,')=',A(i,j)
  enddo
enddo
```

end program test_evs

The next step is to compile and link the program. In order to link the program to Lapack we have to instruct the linker ld where to find the libraries Lapack and BLAS and link them to our program. A library contains compiled software in archives of object files. The convention for their names in a Unix environment is to start with the string “lib” followed by the name of the library and a .a or .so extension. For example, in our case the files we are interested in have the names liblapack.so and libblas.so which can be searched in the file system by the commands:

```bash
> locate libblas
> locate liblapack
```

In order to see the files that they contain we give the commands:

```bash
> ar -t /usr/lib/libblas.so
> ar -t /usr/lib/liblapack.so
```

In the commands shown above you may have to substitute /usr/lib with the path appropriate for your system. If the program is in the file test.f90, the compilation/linking command is:

```
4The library BLAS contains the basic linear algebra subroutines used by Lapack. In some versions of the library, one has to only link to Lapack ignoring the link BLAS but in some other version, linking to BLAS is necessary.

5If the .so files don’t exist in your system, try ar -t /usr/lib/libblas.a etc.
9.2. CALCULATION OF THE EIGENVALUES OF $H_{NM}(\lambda)$

The option `-L/usr/lib` instructs the linker to look for libraries in the `/usr/lib` directory, whereas the options `-llapack -lblas` instructs the linker to look for any *unresolved symbols* (i.e. names of external functions and subroutines not coded in our program) *first* in the library `liblapack.a` and *then* in the library `libblas.a`.

The command shown above produces the executable file `test` which, when run, produces the result:

```plaintext
> gfortran test.f90 -o test -L/usr/lib -llapack -lblas
```

We are now ready to tackle the problem of computing the energy spectrum of the anharmonic oscillator. The main program contains the user interface where the basic parameters for the calculation are read from the stdin. The user can specify the dimension $\text{DIM} \equiv N$ of $\mathcal{H}_N$ and the coupling constant $\lambda$. Then the program computes the eigenvalues $E_n(N, \lambda)$.

---

*This is not necessary in our case, since `/usr/lib` is in the *path* that *ld* searches anyway. This option is useful for libraries located in non conventional paths.*
of the $N \times N$ matrix $H_{nm}(\lambda)$, which represents the action of the operator $H(\lambda)$ in the $\{|n\rangle\}_{n=0,1,\ldots,N-1}$ representation in $\mathcal{H}_N$. The tasks are allocated to the subroutines calculate_X4, calculate_evs and calculate_H. The subroutine calculate_X4 calculates the $N \times N$ matrix $(x^4)_{nm}$. First, the matrix $x_{nm}$ is calculated and then $(x^4)_{nm}$ is obtained by computing its fourth power. The matrix $(x^4)_{nm}$ can also be calculated analytically and this is left as an exercise to the reader. The subroutine calculate_H calculates the matrix $H_{nm}(\lambda)$ using the result for $(x^4)_{nm}$ given by calculate_X4. Finally the eigenvalues are calculated in the subroutine calculate_evs by a call to DSYEV, which are returned to the main program for printing to the stdout. The program is listed below and can be found in the file anharmonic.f90:

```fortran

9.3 Results

Compiling and running the program can be done with the commands:

```bash
> gfortran -O2 anharmonic.f90 -o an -llapack -lblas
> ./an
```

# Enter Hilbert Space dimension:
4

# Enter lambda:
9.3. RESULTS

Figure 9.1: The ground state energy $E_0(\lambda)$ for $\lambda = 0.2, 0.9$ is calculated in the large $N$ limit of the eigenvalues $E_0(N, \lambda)$. Convergence is satisfactory for relatively small values of $N$ and it is slightly faster for $\lambda = 0.2$ than it is for $\lambda = 0.9$.

In the above program we used $N = 4$ and $\lambda = 0$. The $\lambda = 0$ choice leads us to the simple harmonic oscillator and we obtain the expected solutions: $H_{nm} = (n + 1/2)\delta_{n,m}$, $E_n = (n + 1/2)$ and the eigenstates (eigenvectors of $H_{nm}$) $|n\rangle_{\lambda=0} = |n\rangle = \sum_{m=0}^{3} \delta_{n,m} |m\rangle$. Similar results can be obtained for larger $N$.

For non zero values of $\lambda$, the finite $N$ calculation contains systematic errors from neglecting all the matrix elements $H_{nm}(\lambda)$ for $n \geq N$ or $m \geq N$. Our program calculates the eigenvalues $E_n(N, \lambda)$ of the finite matrix $H_{nm}(\lambda)$, $m, n = 0, \ldots, N - 1$ and one expects that

$$E_n(\lambda) = \lim_{N \to \infty} E_n(N, \lambda),$$

(9.22)
where
\[ H(\lambda)\,|n\rangle = E_n(\lambda)\,|n\rangle, \tag{9.23} \]
is the true \(n\)-th level eigenvalue of the Hamiltonian \(H(\lambda)\). In practice the limit \(9.22\) for given \(\lambda\) and \(n\) is calculated by computing \(E_n(N, \lambda)\) numerically for increasing values of \(N\). If convergence to a desired level of accuracy is achieved for the accessible values of \(N\), then the approached limit is taken as an approximation to \(E_n(\lambda)\). This process is shown graphically in figures 9.1-9.3 for \(\lambda = 0.2, 0.9\). Convergence is satisfactory for quite small \(N\) for \(n = 0, 9\) but larger values of \(N\) are needed for \(n = 20\). Increasing the value of \(n\) for fixed \(\lambda\) makes the use of larger values of \(N\) necessary. Similarly for a given energy level \(n\), increasing \(\lambda\) also makes the use of larger values of \(N\) necessary. A session that computes this limit for the ground level energy \(E_0(\lambda = 0.9)\) is shown below:\[7\]

```
> tcsh
> gfortran -02 anharmonic.f90 -llapack -lblas -o an
> foreach N (4 8 12 16 24 32)
>   foreach N (echo $N; echo 0.9) l./an >> data
> foreach? end
> grep ^EV data | awk '{ print $2,$4}'
4  0.71467845686790
8  0.786328966767866
12 0.785237674919165
```

\[7\] The foreach loop construct is special to the tcsh shell. This is why an explicit tcsh command is shown. For other shells use their corresponding syntax.
Figure 9.3: The 20th excited state $E_{20}(\lambda)$ for $\lambda = 0.2, 0.9$ is given by the large $N$ limit of the eigenvalues $E_{20}(N, \lambda)$. Convergence has not been achieved for the displayed values of $N \leq 80$.

Further automation of this process can be found in the shell script file anharmonic.csh in the accompanying software. We note the large $N$ convergence of $E_0(N, 0.9)$ and that we can take $E_0(0.9) \approx 0.78503$. For higher accuracy, a computation using larger $N$ will be necessary.

We can also compute the expectation values $\langle A \rangle_n(\lambda)$ of an operator $A = A(p, q)$ when the anharmonic oscillator is in a state $|n\rangle_\lambda$:

$$\langle A \rangle_n(\lambda) = \lambda \langle n | A | n \rangle_\lambda.$$  \hspace{1cm} (9.24)

In practice, the expectation value will be computed from the limit

$$\langle A \rangle_n(\lambda) = \lim_{N \to \infty} \langle A \rangle_n(N, \lambda) = \lim_{N \to \infty} N, \lambda \langle n | A | n \rangle_N, \lambda,$$ \hspace{1cm} (9.25)

where $|n\rangle_{N, \lambda}$ are the eigenvectors of the finite $N \times N$ matrix $H_{nm}(\lambda)$ computed numerically by DSYEV. These are determined by their components $c_m(N, \lambda)$, where

$$|n\rangle_{N, \lambda} = \sum_{m=0}^{N-1} c_m(N, \lambda) |m\rangle,$$ \hspace{1cm} (9.26)

which are stored in the columns of the array $H$ after the call to DSYEV:

$$c_m(N, \lambda) = H(m + 1, n + 1).$$ \hspace{1cm} (9.27)
CHAPTER 9. THE ANHARMONIC OSCILLATOR

Substituting equation (9.26) to (9.24) we obtain

\[ \langle A \rangle_n(\lambda) = \sum_{m,m'}^{N-1} c_m(N, \lambda)c_{m'}(N, \lambda)A_{mm'}, \]  

(9.28)

and we can use (9.27) for the computation of the sum.

As an application, consider the expectation values of the operators \( x^2, x^4 \) and \( p^2 \). Taking into account that \( \langle x \rangle_n = \langle p \rangle_n = 0 \), we obtain the uncertainties \( \Delta x_n \equiv \sqrt{\langle x^2 \rangle_n - \langle x \rangle_n^2} = \sqrt{\langle x^4 \rangle_n} \) and \( \Delta p_n = \sqrt{\langle p^2 \rangle_n} \). Their product should satisfy Heisenberg’s uncertainty relation \( \Delta x_n \cdot \Delta p_n \gtrsim 1/2 \). The results are shown in table 9.1 and in figures 9.4–9.5. The calculation is left as an exercise to the reader.

![Figure 9.4: The expectation values \( \langle x^2 \rangle_{n}^{1/2}(\lambda), \langle p^2 \rangle_{n}^{1/2}(\lambda) \) and the product of uncertainties \( \Delta x_n \cdot \Delta p_n \) for \( n = 9 \) and \( \lambda = 0.5 \) calculated from the large \( N \) limits of \( \langle x^2 \rangle_{n}^{1/2}(N, \lambda), \langle p^2 \rangle_{n}^{1/2}(N, \lambda) \).](image)

The physics of the anharmonic oscillator can be better understood by studying the large \( \lambda \) limit. As shown in figure 9.5, the term \( \lambda x^4 \) dominates in this limit and the expectation value \( \langle x^2 \rangle_{n}(\lambda) \) decreases. This means that states that confine the oscillator to a smaller range of \( x \) are favored. This, using the uncertainty principle, implies that the typical momentum of the oscillator also increases in magnitude. This is confirmed in figure 9.5 where we observe the expectation value \( \langle p^2 \rangle_{n}(\lambda) \) to increase with \( \lambda \). In order to understand quantitatively these competing effects we will use a scaling argument due to Symanzik. We redefine \( x \rightarrow \lambda^{-1/6}x, p \rightarrow \lambda^{1/6}p \) in the Hamiltonian \( H(\lambda) = p^2/2 + x^2/2 + \lambda x^4 \) and for large enough \( \lambda \) we
obtain the asymptotic behavior

$$H(\lambda) \sim \lambda^{1/3} h(1), \quad \lambda \to \infty,$$

(9.29)

where $h(\lambda) = p^2/2 + \lambda x^4$ is the Hamiltonian of the anharmonic “oscillator” with $\omega = 0$. Since the operator $h(1)$ is independent of $\lambda$, the energy spectrum will have the asymptotic behavior

$$E_n(\lambda) \sim C_n \lambda^{1/3}, \quad \lambda \to \infty.$$

(9.30)

In reference [42] it is shown that for $\lambda > 100$ we have that

$$E_0(\lambda) = \lambda^{1/3} \left(0.66798625918 + 0.1436718 \lambda^{-2/3} - 0.0088 \lambda^{-4/3} + \ldots\right),$$

(9.31)

with an accuracy better than one part in $10^6$. For large values of $n$, the authors obtain the asymptotic behavior

$$E_n(\lambda) \sim C \lambda^{1/3} \left(n + \frac{1}{2}\right)^{4/3}, \quad \lambda \to \infty, n \to \infty,$$

(9.32)

where $C = 3^{4/3} \pi^2 / \Gamma(1/4)^{8/3} \approx 1.37650740$. This relation is tested in figure 9.6 where we observe good agreement with our calculations.

*For $x \to \lambda^{-1/6} x$, $H \to \lambda^{1/3}(p^2/2 + \lambda^{-2/3} x^2/2 + x^4)$, therefore in the limit $\lambda \to \infty$ the second term vanishes and we obtain equation (9.29).*
CHAPTER 9. THE ANHARMONIC OSCILLATOR

\[ \lambda = 0.5 \]

\[
\begin{array}{|c|c|c|c|c|c|c|}

\hline
\end{array}
\]

Table 9.1: The expectation values \( \langle x^2 \rangle, \langle p^2 \rangle, \Delta x \cdot \Delta p \) for the anharmonic oscillator for the states \( \ket{n}, n = 0, \ldots, 9 \). We observe a decrease of \( \Delta x = \sqrt{\langle x^2 \rangle} \) and an increase of \( \Delta p = \sqrt{\langle p^2 \rangle} \) as \( \lambda \) is increased. The product \( \Delta x \cdot \Delta p \) seems to remain very close to the values \( (n + 1/2) \) of the harmonic oscillator for both values of \( \lambda \).

9.4 The Double Well Potential

We can also use matrix methods in order to calculate the energy spectrum of a particle in a double well potential given by the Hamiltonian:

\[ H = \frac{p^2}{2} - \frac{x^2}{2} + \lambda \frac{x^4}{4}. \]  

(9.33)

The equilibrium points of the classical motion are located at the minima:

\[ x_0 = \pm \frac{1}{\sqrt{\lambda}}, V_{\text{min}} = -\frac{1}{4\lambda}. \]  

(9.34)

When the well is very deep, then for the lowest energy levels the potential can be well approximated by that of a harmonic oscillator with angular frequency \( \omega^2 = V''(x_0) \), therefore

\[ E_{\text{min}} \approx V_{\text{min}} + \frac{1}{2} \omega. \]  

(9.35)

In this case the tunneling effect is very weak and the energy levels are arranged in almost degenerate pairs. The corresponding eigenstates are symmetric and antisymmetric linear combinations of states localized near the left and right minima of the potential. For example, for the two lowest

</table>
energy levels we expect that

\[ E_{0,1} \approx E_{\text{min}} \pm \Delta \frac{\Delta}{2}, \quad (9.36) \]

where \( \Delta \ll |E_{\text{min}}| \) and

\[ |0\rangle_\lambda \approx \frac{|+\rangle + |-\rangle}{\sqrt{2}}, \quad |1\rangle_\lambda \approx \frac{|+\rangle - |-\rangle}{\sqrt{2}}, \quad (9.37) \]

where the states \( |+\rangle \) and \( |-\rangle \) are localized to the left and right well of the potential respectively (see also figure 10.4 of chapter 10).

We will use equations (9.12) in order to calculate the Hamiltonian (9.33). We need to make very small modifications to the code in the file anharmonic.f90. We will only add a routine that calculates the matrices \( p_{nm} \). The resulting program can be found in the file doublewell.f90:

end subroutine calculate_operators

Where is the particle’s favorite place when it is in the states $|+\rangle$ and $|\rangle$? The answer to this question is obtained from the study of the expectation value of the position operator $\langle x \rangle$ in each one of them. We know that when the particle is in one of the energy eigenstates, then we have that

$$\langle x \rangle_n(\Lambda) = \chi(n|x|n)_\Lambda = 0$$

(9.38)

because the potential $V(x) = V(-x)$ is even. Therefore

$$\langle x \rangle_\pm(\Lambda) = \langle \pm |x| \pm \rangle = \frac{1}{\sqrt{2}} (\chi(0|x|0)_\Lambda \pm \chi(1|x|1)_\Lambda) \pm \chi(0|x|1)_\Lambda + \chi(1|x|0)_\Lambda$$

(9.39)

where in the last line we used the relation (9.38) $\chi(0|x|0)_\Lambda = \chi(1|x|1)_\Lambda = 0$ and that the amplitudes $\chi(1|x|0)_\Lambda = \chi(0|x|1)_\Lambda$. Also $\chi(1|x|0)_\Lambda > 0$. Therefore, if we have that $|0\rangle_\Lambda = \sum_{m=0}^{\infty} c_m^{(0)} |m\rangle$ and $|1\rangle_\Lambda = \sum_{m=0}^{\infty} c_m^{(1)} |m\rangle$, we obtain

$$\langle x \rangle_\pm(\Lambda) = \pm \sqrt{2} \sum_{m,m'=0}^{\infty} c_m^{(0)} c_m^{(1)} X_{mm'}.$$  

(9.40)

Given that for finite $N$, the subroutine DSYEV returns approximations to the coefficients $c_m^{(n)}$ in the columns of the matrix $H(DIM, DIM)$ so that $c_m^{(n)} \approx H(n+1,n+1)$, you may compare the value of $\langle x \rangle_\pm(\Lambda)$ with the classical values $x_0 = \pm 1/\sqrt{\lambda}$ as $\lambda$ is increased.

---

9You may convince yourselves by looking at the wave functions in figures 10.4 of chapter 10 and by computing the relevant integrals.
Figure 9.8: Calculation of the difference of the energy levels \( \Delta_n = E_{n+1} - E_n \) for \( n = 0, 6, 30 \) for the double well potential from the program `doublewell.f90`. The difference vanishes as the well becomes deeper with decreasing \( \lambda \). The states \(| \pm \rangle = (|n+1\rangle \pm |n\rangle \lambda)/\sqrt{2} \) are more and more localized to the right or left well respectively.
9.5 Problems

9.1 Calculate the matrix $H(\lambda)$ for $N = 2, 3$ analytically. Calculate its eigenvalues for $N = 2$. Compare your results with the numerical values that you obtain from your program.

9.2 Add the necessary code to the program in the file test.f90 so that it checks that the eigenvectors satisfy their defining relations $A \mathbf{v}_i = \lambda_i \mathbf{v}_i$ and that they form an orthonormal basis $\mathbf{v}_i \cdot \mathbf{v}_j = \delta_{ij}$.

9.3 Calculate $E_5(\lambda)$ and $E_9(\lambda)$ for $\lambda = 0.8, 1.2$ with an accuracy better than 0.01%.

9.4 For how large $n$ can you calculate $E_n(\lambda)$ for $\lambda = 1$ with an accuracy better than 2% when $N = 64$?

9.5 Calculate $E_3(\lambda)$ and $E_{12}(\lambda)$ for $0 \leq \lambda \leq 4$ with step $\delta \lambda = 0.2$ by achieving accuracy better than 0.01%. How large should $N$ be taken in each case?

9.6 Calculate the expression that gives the matrix elements of the operator $x^4$ in the $|n\rangle$ representation analytically. Modify the program in anharmonic.f90 in order to incorporate your calculation. Verify that the results are the same and test if it has an effect in the total computation time with and without calculating the eigenvalues and eigenvectors of the Hamiltonian. Compute in each case the dependence of the cpu time on $N$ by computing the exponent (cpu time)$\sim N^a$ for $N = 40 - 1000$.

9.7 Modify the code in the file anharmonic.f90 so that the arrays $H$, $X$, $X4$, $E$, WORK are ALLOCATABLE and their dimension is determined by the variable DIM read by the program interactively.

9.8 Make an attempt to reproduce the results of Hioe and Montroll [42] given in table 9.2 for $n = 3$ and $n = 5$. What is the largest value of $\lambda$ that you can study given your computational resources?

9.9 Make an attempt to reproduce the results of Hioe and Montroll [42] given by equation (9.31). Calculate the ground state energy $E_0$ for $200 < \lambda < 20000$ and then fit your results to a function of the form $\lambda^{1/3}(a + b\lambda^{-2/3} + c\lambda^{-4/3})$. What is the accuracy in the calculation of the coefficients $a$, $b$ and $c$ and how good is the agreement with equation (9.31)?
9.10 Modify the code in the file anharmonic.f90 so that it calculates the expectation values \( \langle x^2 \rangle_n(N, \lambda) \), \( \langle p^2 \rangle_n(N, \lambda) \) and the corresponding products \( \Delta x \cdot \Delta p \).
(Hint: See the file anharmonicOBS.f90.)

9.11 Reproduce the results shown in figure 9.4. Repeat your calculation for \( \lambda = 2.0, 10.0, 100.0 \). Repeat your calculations for \( n = 20 \).

9.12 Reproduce the results shown in figure 9.5. Repeat your calculations for \( n = 20 \).

9.13 Reproduce the results shown in figure 9.6. Repeat your calculation for \( n = 3, 7, 12, 18, 24 \).

9.14 Write a program that calculates the energy levels of the anharmonic oscillator
\[
H(\lambda, \mu) = \frac{1}{2} p^2 + \frac{1}{2} x^2 + \lambda x^4 + \mu x^6 .
\] (9.41)
Calculate \( E_n(\lambda) \) for \( n = 0, 3, 8, 20 \), \( \lambda = 0.2 \) and \( \mu = 0.2, 0.5, 1.0, 2.0, 10.0 \).

9.15 Modify the program of the previous problem so that it calculates the expectation values \( \langle x^2 \rangle_n(N, \lambda) \), \( \langle p^2 \rangle_n(N, \lambda) \) and the products \( \Delta x \cdot \Delta p \). Calculate the expectation values \( \langle x^2 \rangle_n(\lambda) \), \( \langle p^2 \rangle_n(\lambda) \) and \( \Delta x \cdot \Delta p \) for \( n = 0, 3, 8, 20 \), \( \lambda = 0.2 \) and \( \mu = 0.2, 0.5, 1.0, 2.0, 10.0 \).

9.16 Use the program doublewell.f90 in order to calculate the energy level pairs \( E_n, E_{n+1} \) for \( n = 0, 4, 20 \) and \( \lambda = 0.2, 0.1, 0.05, 0.02 \). Calculate the difference \( \Delta_n = E_{n+1} - E_n \) and comment on your results.

9.17 Define the energy values
\[
\epsilon_n = -\frac{1}{4\lambda} + \left( n + \frac{1}{2} \right) .
\]
Compare the results for \( E_n, E_{n+1} \) of the previous problem with \( \epsilon_n - \Delta_n/2 \) and \( \epsilon_n + \Delta_n/2 \) respectively. Explain your results.

9.18 Modify the program doublewell.f90, so that it calculates the expectation values \( \langle x \rangle_{\pm}(\lambda) \) given by equation (9.40). Compare \( \langle x \rangle_{\pm}(\lambda) \) with the classical values \( x_0 = \pm 1/\sqrt{\lambda} \) for \( \lambda = 0.2, 0.1, 0.05, 0.02, 0.01 \).

9.19 Repeat the previous problem when the states \( |\pm\rangle = (1/\sqrt{2})(|n\rangle_{\lambda} \pm |n+1\rangle_{\lambda}) \) for \( n = 6 \) and \( n = 30 \).
9.20 For the simple harmonic oscillator, the energy levels are equidistant, i.e. \( \Delta_n = E_{n+1} - E_n = 1 \). \((\Delta_{n+2} - \Delta_n)/\Delta_n = 0\). Calculate these quantities for the anharmonic oscillator and the double well potential for \( \lambda = 1, 10, 100, 1000 \) and \( n = 0, 8, 20 \). What do you conclude from your results?
Chapter 10

Time Independent Schrödinger Equation

In this chapter, we will study the time independent Schrödinger equation for a non relativistic particle of mass \( m \), without spin, moving in one dimension, in a static potential \( V(x) \). We will only study bound states. The solutions in this case yield the discrete energy spectrum \( \{ E_n \} \) as well as the corresponding eigenstates of the Hamiltonian \( \{ \psi_n(x) \} \) in position representation.

From a numerical analysis point of view, the problem consists of solving for the eigensystem of a differential equation with boundary conditions. Part of the solution is the energy eigenvalue which also needs to be determined.

As an exercise, we will use two different methods, one that can be applied to a particle in an infinite well with \( V(x) = V(-x) \), and one that can be applied to more general cases. The first method is introduced only for educational purposes and the reader may skip section 10.2 to go directly to section 10.3.

10.1 Introduction

The wave functions \( \psi(x) \), which are the position representation of the energy eigenstates, satisfy the Schrödinger equation

\[
-\frac{\hbar^2}{2m} \frac{\partial^2 \psi(x)}{\partial x^2} + V(x)\psi(x) = E\psi(x),
\]

(10.1)
with the normalization condition
\[ \langle \psi | \psi \rangle = \int_{-\infty}^{+\infty} \psi^* (x) \psi (x) \, dx = 1. \quad (10.2) \]

The Hamiltonian operator is given in position representation by
\[ \hat{H} = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + V (\hat{x}), \quad (10.3) \]

and it is Hermitian, i.e. \( \hat{H}^\dagger = \hat{H} \). Equation (10.1) is an eigenvalue problem
\[ \hat{H} \psi (x) = E \psi (x), \quad (10.4) \]
which, for bound states, has as solutions a discrete set of real functions \( \psi_n^* (x) = \psi_n (x) \) such that \( \hat{H} \psi_n (x) = E_n \psi_n (x) \). The numbers \( E_0 \leq E_1 \leq E_2 \leq \ldots \) are real and they are the (bound) energy spectrum of the particle in the potential \( V (x) \). The minimum energy \( E_0 \) is called the ground state energy and the corresponding ground state is given by a non trivial function \( \psi_0 (x) \). According to the Heisenberg uncertainty principle, in this state the uncertainties in momentum \( \Delta p > 0 \) and position \( \Delta x > 0 \) so that \( \Delta p \cdot \Delta x \geq \hbar / 2 \).

The eigenstates \( \psi_n (x) \) form an orthonormal basis
\[ \langle \psi_n | \psi_m \rangle = \int_{-\infty}^{+\infty} \psi_n^* (x) \psi_m (x) \, dx = \delta_{n,m}. \quad (10.5) \]

so that any (square integrable) wave function \( \phi (x) \) which represents the state \( |\phi\rangle \) is given by the linear combination
\[ \phi (x) = \sum_{n=0}^{\infty} c_n \psi_n (x). \quad (10.6) \]

The amplitudes \( c_n = \langle \psi_n | \phi \rangle = \int_{-\infty}^{+\infty} \psi_n^* (x) \phi (x) \, dx \) are complex numbers that give the probability \( p_n = |c_n|^2 \) to measure energy \( E_n \) in the state \( |\phi\rangle \).

For any state \( |\phi\rangle \) the function
\[ p_\phi (x) = |\phi (x)|^2 = \phi^* (x) \phi (x) \quad (10.7) \]

The fact that the energy spectrum of the particle is bounded from below depends on the form of the potential. We assume that \( V (x) \) is such that \( E_0 \) is finite. Also, in one dimension, the energy spectrum of a particle for reasonable potentials is non degenerate (see, however, S. Kar, R. Parwani, arXiv:0706.1135.)
is the probability density of finding the particle at position \( x \), i.e. the probability of detecting the particle in the interval \([x_1, x_2]\) is given by

\[
P_\phi(x_1 < x < x_2) = \int_{x_1}^{x_2} p_\phi(x) \, dx = \int_{x_1}^{x_2} \phi^*(x)\phi(x) \, dx.
\] (10.8)

The normalization condition (10.2) reflects the conservation of probability (independent of time, respected by the time dependent Schrödinger equation) and the completeness (in this case the certainty that the particle will be observed somewhere on the \( x \) axis).

The classical observables \( \mathcal{A}(x, p) \) of this quantum mechanical system are functions of the position and the momentum and their quantum mechanical versions are given by operators \( \hat{\mathcal{A}}(\hat{x}, \hat{p}) \). Their expectation values when the system in a state \( |\phi\rangle \) are given by

\[
\langle \hat{\mathcal{A}} \rangle_\phi = \langle \phi | \hat{\mathcal{A}} | \phi \rangle = \int_{-\infty}^{+\infty} \phi^*(x)\hat{\mathcal{A}}(\hat{x}, \hat{p})\phi(x) \, dx.
\] (10.9)

From a numerical point of view, the eigenvalue problem (10.1) requires the solution of an ordinary second order differential equation. There are certain differences in this problem compared to the ones studied in previous sections:

- Instead of an initial value problem (i.e. the values of the function and its derivative are given at one point), we have a boundary value problem (values of the function or its derivative given at two different points).
- The eigenvalue (energy) is unknown and should be determined as part of the solution.

As an introduction to such classes of problems, we will present some simple methods which are special to one dimension.

For the numerical solution of the above equation we renormalize \( x \), the function \( \psi(x) \) and the parameters so that we deal only with dimensionless quantities. Equation (10.1) is rewritten as:

\[
\frac{d^2}{dx^2} \psi(x) + \frac{2m}{\hbar^2} (E - V(x))\psi(x) = 0.
\] (10.10)

Then we choose a length scale \( L \) which is defined by the parameters of the problem\footnote{There are \( m, \hbar \) and the coupling constants in the function \( V(x) \). The range of the potential will determine \( L \) in some problems and it is given explicitly in potential wells. In potentials of real physical systems, however, this is also determined by the coupling constants.} and we redefine \( \tilde{x} = x/L \). We define \( \tilde{\psi}(\tilde{x}) = \psi(x) \tilde{\psi}'(\tilde{x}) = \psi(x) \).
\( d\psi(x)/dx = L d\psi(x)/dx \) and we obtain
\[
\tilde{\psi}''(\tilde{x}) + \frac{2mL^2}{\hbar^2}(E - V(\tilde{x}L))\tilde{\psi}(\tilde{x}) = 0.
\] (10.11)

We define \( v(\tilde{x}) = 2mL^2V(x)/\hbar^2 = 2mL^2V(\tilde{x}L)/\hbar^2 \), \( \epsilon = 2mL^2E/\hbar^2 \) and change notation to \( \tilde{x} \rightarrow x, \tilde{\psi} \rightarrow \psi \). We obtain
\[
\psi''(x) = -(\epsilon - v(x))\psi(x).
\] (10.12)

The solutions of equation (10.1) can be obtained from those of equation (10.12) by using the following “dictionary”:
\[
x \rightarrow \frac{x}{L}, \quad E = \frac{\hbar^2}{2mL^2}\epsilon, \quad V(x) = \frac{\hbar^2}{2mL^2}v(x/L).
\] (10.13)

The dimensionless momentum is defined as \( \tilde{p} = -i\partial/\partial \tilde{x} = -iL\partial/\partial x \) and we obtain
\[
\tilde{p} = \frac{L}{\hbar}\tilde{p}.
\] (10.14)

The commutation relation \([x, p] = i\hbar\) becomes \([\tilde{x}, \tilde{p}] = i\). The kinetic energy \( T = \frac{\tilde{p}^2}{2m} \) is given by
\[
T = \frac{\hbar^2}{2mL^2}\tilde{p}^2 = -\frac{\hbar^2}{2mL^2}\frac{\partial^2}{\partial \tilde{x}^2},
\] (10.15)

and the Hamiltonian \( H = T + V \)
\[
H = \frac{\hbar^2}{2mL^2}\left(\tilde{p}^2 + v(\tilde{x})\right) = \frac{\hbar^2}{2mL^2}\left(-\frac{\partial^2}{\partial \tilde{x}^2} + v(\tilde{x})\right).
\] (10.16)

In what follows, we will omit the tilde above the symbols and write \( x \) instead of \( \tilde{x} \).

### 10.2 The Infinite Potential Well

The simplest model for studying the qualitative features of bound states is the infinite potential well of width \( L \) where a particle is confined within the interval \([-L/2, L/2]\):

\[
v(x) = \begin{cases} 
0 & |x| < 1 \\
\infty & |x| \geq 1
\end{cases}
\] (10.17)

---

\(^3\)If we normalize the solutions \( \tilde{\psi}(\tilde{x}) \) of equation (10.12) according to the relation \( \int_{-\infty}^{+\infty} \tilde{\psi}^*(\tilde{x})\tilde{\psi}(\tilde{x}) d\tilde{x} = 1 \), we should also take \( \psi(x) = (1/\sqrt{L})\tilde{\psi}(x/L) \) in order to be properly normalized \( \int_{-\infty}^{+\infty} \psi^*(x)\psi(x) dx = 1 \).
10.2. THE INFINITE POTENTIAL WELL

The length scale chosen here is $L/2$ and the dimensionless variable $x$ corresponds to $x/(L/2)$ when $x$ is measured in length units.

The solution of (10.12) can be easily computed. Due to the symmetry

$$v(-x) = v(x),$$

(10.18)

of the potential, the solutions have well defined parity. This property will be crucial to the method used below. The method discussed in the next section can also be used on non even potentials.

The solutions are divided into two categories, one with even parity $\psi_n(x) \equiv \psi_n^+(x) = \psi_n^-(x)$ for $n = 1, 3, 5, 7, \ldots$ and one with odd parity $\psi_n(x) \equiv -\psi_n^-(x) = \psi_n^+(x)$ for $n = 2, 4, 6, 8, \ldots$

$$\psi_n(x) = \begin{cases} 
\psi_n^+(x) = \cos \left( \frac{n\pi}{2} x \right) & |x| < 1 \quad n = 1, 3, 5, 7, \ldots \\
\psi_n^-(x) = \sin \left( \frac{n\pi}{2} x \right) & |x| < 1 \quad n = 2, 4, 6, 8, \ldots
\end{cases}$$

(10.19)

where

$$\epsilon_n = \left( \frac{n\pi}{2} \right)^2,$$

(10.20)

and the normalization has been chosen so that $\int_{-1}^{1} (\psi_n(x))^2 \, dx = 1$.

---

4According to the dictionary mentioned in the previous section, for a potential well where $x \in [-L/2, L/2]$ the dimensionless position variable has been chosen to be $x/(L/2) \in [-1, 1]$. Then $E_n = \frac{\hbar^2}{2m(L/2)^2} \epsilon_n = \frac{\hbar^2 \pi^2}{2mL^2} n^2$ and $\psi_n^+(x) = \sqrt{2/L} \cos(n\pi x/L)$, $\psi_n^-(x) = \sqrt{2/L} \sin(n\pi x/L)$. Note that $\epsilon_n = p_n^2$ according to equations (10.13) and (10.14).
The solutions can be found by using the parity of the wave functions. We note that for the positive parity solutions
\[ \psi^{(+)}_n(0) = A \quad \psi^{(+)}_n'(0) = 0 , \] (10.21)
whereas for the negative parity solutions
\[ \psi^{(-)}_n(0) = 0 \quad \psi^{(-)}_n'(0) = A . \] (10.22)

The constant \( A \) depends on the normalization of the wave function. Therefore we can set \( A = 1 \) originally and then renormalize the wave function so that equation (10.2) is satisfied. If the energy is known, the relations (10.21) and (10.22) can be taken as initial conditions in relation (10.12). By using a Runge–Kutta algorithm we can evolve the solution towards \( x = \pm 1 \). The problem is that the energy \( \epsilon \) is unknown. If the energy is not allowed by the quantum theory we will find that the boundary conditions
\[ \psi^{(\pm)}_n(\pm 1) = 0 \] (10.23)
are violated. As we approach the correct value of the energy, we obtain \( \psi^{(\pm)}_n(\pm 1) \to 0 \).

Therefore we follow the steps described below:

- We choose an initial value for the energy \( \epsilon \) that is lower than the one we are looking for. We can use estimates from known solutions of
similar looking potential wells or simply start from a value slightly higher than the absolute minimum of the potential.

- We choose the parity of the solution and we set initial conditions according to equations (10.21) and (10.22).
- We evolve the solutions using a 4th order Runge-Kutta method from $x=0$ to $x=+1$.
- If equation (10.23) is not satisfied, we increase the energy by $\delta \epsilon$ and we repeat.
- We repeat until $\psi_n^{(\pm)}(1)$ changes sign. Then we lower the energy by $\delta \epsilon = -\delta \epsilon / 2$.
- The process is ended when $|\psi_n^{(\pm)}(1)| < \delta$ for appropriately chosen small $\delta$.

For the evolution of the solution from $x=0$ to $x=1$ we use the 4th order Runge-Kutta method programmed in the file `rk.f90` of chapter 4. We copy the subroutine `RKSTEP` in a local file `rk.f90`. The integration of (10.12) can by done by using the function $\phi(x) \equiv \psi'(x)$

\[ \psi'(x) = \phi(x) \]
\[ \phi'(x) = (v(x) - \epsilon)\psi(x), \quad (10.24) \]

with the initial conditions

\[ \psi(0) = 1 \quad , \quad \phi(0) \equiv \psi'(0) = 0 \quad \text{even parity} \]
\[ \psi(0) = 0 \quad , \quad \phi(0) \equiv \psi'(0) = 1 \quad \text{odd parity}. \quad (10.25) \]

We use the notation $\psi(x) \rightarrow \text{psi}$, $\phi(x) \rightarrow \text{psip}$. The functions $f1$ and $f2$ correspond to the right hand side of (10.24). They are the derivatives of $\psi(x)$ and $\phi(x)$ respectively and $f1=\text{psip}$, $f2=(V\text{-energy})*\psi$. The code of $f1$ and $f2$ is put in a different file so that we can easily reuse the code for many different potentials $v(x)$. The file `wellInfSq.f90` contains the necessary program for the potential of equation (10.17):

```fortran
!========================================================================
! file: wellInfSq.f
!
! Functions used in RKSTEP routine. Here:
```

\footnote{The function in $[-1,0)$ is determined by the parity of the solution.}
We stress that the energy $\epsilon = \text{energy}$ is put in a common block so that it can be accessed by the main program.

The main program is in the file well.f90. The user enters the parameters (energy, parity, $N_x$) and the loop

```fortran
  do while (iter .lt. 10000)
    .........
    if (DABS(psinew) .le. epsilon) EXIT
    if (psinew*psiold .lt. 0.0D0 ) de = -0.5D0*de
    energy = energy + de
    .........
  enddo
```

exists when $\psi(1) = \text{psinew}$ has an absolute value which is less than $\text{epsilon}$, i.e. when the condition (10.23) is satisfied to the desired accuracy. The value of the energy increases up to the point where the sign of the wave function at $x = 1$ changes ($\text{psinew}^*\text{psiold} < 0$). Then the value of the energy is overestimated and we change the sign of the step $\text{de}$ and reduce its magnitude by a half. The algorithm described on page 406 is implemented inside the loop. After exiting the loop, the energy has been determined with the desired accuracy and the rest of the program stores the solution in the array $\text{psifinal}(\text{STEPS})$. The results are written to the
file psi.dat. Note how the variable parity is used so that both cases parity=±1 can be studied. The full program is listed below:

10.2. THE INFINITE POTENTIAL WELL

The energy is determined to be $\epsilon = 2.467401123$ which can be compared to the exact value $\epsilon = (\pi/2)^2 \approx 2.467401100$. The fractional error is $\sim 10^{-8}$. The convergence can be studied graphically in figure 10.2.

The calculation of the excited states is done by changing the parity and by choosing the initial energy slightly higher than the one determined in the previous step⁵. The results are in table 10.1. The agreement with the exact result $\epsilon_n = (n\pi/2)^2$ is excellent.

We close this section with two more examples. First, we study a potential well with triangular shape at its bottom

$$v(x) = \begin{cases} 
    v_0|x| & |x| < 1 \\
    +\infty & |x| > 1
\end{cases}$$

⁵Careful: if the energy levels are too close, we should keep the initial energy constant and change the sign of parity.
Table 10.1: Energy eigenvalues for the square, triangular and double well potentials (equations (10.17), (10.26) with $v_0 = 10$ and equation (10.27) with $v_0 = 100, a = 0.3$). The agreement of the results for the square potential with the exact ones is excellent. For the other potentials, we note that as we move further from the bottom of the well we obtain energy levels very close to those of the square well: The particle does not feel the influence of the details at the bottom of the well. For the double well potential we obtain $E_1 \approx E_2$ and $E_3 \approx E_4$ according to the analysis on page 413.
and then a double well potential with

\[
v(x) = \begin{cases} 
  v_0 & |x| < a \\
  0 & a < |x| < 1 \\
  +\infty & 1 < |x|
\end{cases}
\]  

(10.27)

where the parameters \( v_0, a \) are positive numbers. A qualitative plot of these functions is shown in figure 10.1.

For the triangular potential we take \( v_0 = 10 \), whereas for the double well potential \( v_0 = 100 \) and \( a = 0.3 \). The code in wellInfSq.f90 is appropriately modified and saved in the files wellInfTr.f90 and wellInfDbl.f90 respectively. All we have to do is to change the line computing the value of the potential in the function f2. For example the file wellInfTr.f90 contains the code

```fortran
!--------- potential, set here:
V = 10.0D0*DAABS(x)
```

whereas the file wellInfDbl.f90 contains the code

```fortran
!--------- potential, set here:
if ( DAABS(x) .le. 0.3D0) then
  V = 100.0D0
else
  V = 0.0D0
endif
```

The analysis is performed in exactly the same way and the results are shown in table [10.1]. Note that, for large enough \( n \), the energy levels of all the potentials that we studied above tend to have identical values. This happens because, when the particle has energy much larger than \( v_0 \), the details of the potential at the bottom do not influence its dynamical properties very much. For the triangular potential, the energy levels have higher values than the corresponding ones of the square potential. This happens because, on the average, the potential energy is higher and the potential tends to confine the particle to a smaller region (\( \Delta x \) is decreased, therefore \( \Delta p \) is increased). This can be seen in figure 10.3 where the wave functions of the particle in each of the two potentials are compared.

Similar observations can be made for the double well potential. Moreover, we note the approximately degenerate energy levels, something which is expected for potentials of this form. This can be understood in terms of the localized states given by the wave functions \( \psi_+(x) = \)
(1/√2)(ψ₁(x) + ψ₂(x)) and ψ₋(x) = (1/√2)(ψ₁(x) − ψ₂(x)). The first one represents a state where the particle is localized in the left well and the second one in the right. This is shown in figure 10.4. As v₀ → +∞ the two wells decouple and the wave functions ψ₊(x) become equal to the energy eigenstate wave functions of two particles in separate infinite square wells of width 1 − a with energy eigenvalues ϵ₊,₁ = ϵ₋,₁ = (π/(1 − a))². The difference of ϵ₁ and ϵ₂ from these two values is due to the finite v₀ (see problem 4).

We will now discuss the limitations of this method. First, the method can be used only on potential wells that are even, i.e. v(x) = v(−x). We used this assumption in equations (10.21) and (10.22) giving the initial conditions for states of well defined parity. When the potential is even, the energy eigenstates have definite parity. The other problem can be

![Wave functions](image-url)
10.3. BOUND STATES

Figure 10.4: The functions $\psi_+(x) = (1/\sqrt{2})(\psi_n(x) \pm \psi_{n+1}(x))$ for $n = 1, 3, 5$ for the double well potential (equation (10.27) with $v_0 = 100, a = 0.3$) are plotted using bold red lines. We observe that the more degenerate the states, the stronger the localization of the particle to the left or right well. The other plots are those of the energy eigenfunctions for $n = 1, 2, 3, 4, 5, 6$.

understood by solving problem 4: When $v(0) \gg \epsilon$, the wave function is almost zero around $x = 0$ and the integration from $x = 0$ to $x = 1$ will be dominated by numerical errors. The same is true when the particle has to go through high potential barriers.

This method can also be used on potential wells that are not infinite. In that case we can add infinite walls at points that are far enough so that the wave function is practically zero there. Then the influence of this artificial wall will be negligible (see problem 3).

10.3 Bound States

A serious problem with the method discussed in the previous section is that it is numerically unstable. You should have already realized that if you tried to solve problem 3. In that problem, when the walls are moved
Figure 10.5: Integration of Schrödinger’s equation by the use of the algorithm of section 10.3. The wave functions and their derivatives are given small trial values at $x_{\text{min}}$ and $x_{\text{max}}$ which are in the classically forbidden regions of $x$. The point $x_m$ is calculated from the equation $v(x_m) = \epsilon$. The wave functions are evolved to $x_m$ according to (10.24) and we obtain the solutions $\psi^{(+)}(x)$ and $\psi^{(-)}(x)$. We renormalize $\psi^{(-)}(x)$ so that $\psi^{(+)}(x_m) = \psi^{(-)}(x_m)$ and we vary the energy until the derivatives $\psi^{(+)}(x_m) \approx \psi^{(-)}(x_m)$.

Further than $|x| = 3$, the convergence of the algorithm becomes harder. You can understand this by realizing that in the integration process the solution is evolved from the classically allowed into the classically forbidden region so that an oscillating solution changes into an exponentially damped one. But as $|x| \to +\infty$ there are two solutions, one that is physically acceptable $\psi(x) \sim e^{-k|x|}$ and one that is diverging $\psi(x) \sim e^{+k|x|}$ which is not acceptable due to (10.2). Therefore, in order to achieve convergence to the physically acceptable solution, the energy has to be finely tuned, especially when we integrate towards large $|x|$. For this reason it is preferable to integrate from the exponentially damped region towards the oscillating region. The idea is to start integrating from these regions and try to match the solutions and their derivatives at appropriately chosen matching points. The matching is achieved at a point $x_m$ by trying to determine the value of the energy that sets the ratio

$$f(\epsilon) = \frac{\psi^{(+)}(x_m)/\psi^{(+)}(x_m) - \psi^{(-)}(x_m)/\psi^{(-)}(x_m)}{\psi^{(+)}(x_m)/\psi^{(+)}(x_m) + \psi^{(-)}(x_m)/\psi^{(-)}(x_m)}$$

(10.28)
equal to zero, within the attainable numerical accuracy. It is desirable to choose a point \( x_m \) within the classical region (\( \epsilon > v(x) \)) and usually we pick a turning point \( \epsilon = v(x) \). By renormalizing \( \psi(\pm)(x) \) we can always set \( \psi(\pm)(x_m) = \psi(-)(x_m) \), therefore \( f(\epsilon) \ll 1 \) means that \( \psi(+)'(x_m) \approx \psi(-)'(x_m) \).

The denominator of \( \text{(10.28)} \) sets the scale of the desired accuracy. The idea is depicted in figure 10.5. The algorithm is the following:

1. Choose the integration interval \([x_{\text{min}}, x_{\text{max}}]\).
2. Choose the initial conditions \( \psi(-)(x_{\text{min}}), \psi(-)'(x_{\text{min}}), \psi(+)(x_{\text{max}}), \psi(+)'(x_{\text{max}}) \). This choice depends on the potential \( v(x) \). Usually we take \( x_{\text{min}} \) and \( x_{\text{max}} \) deep enough in the classically forbidden region and choose the values \( \psi(-)(x_{\text{min}}), \psi(+)(x_{\text{max}}) \) to be zero or exponentially small (e.g. \( \sim e^{-k|x|}, k^2 = v(x) - \epsilon \)). The corresponding values of the derivatives \( \psi(-)'(x_{\text{min}}), \psi(+)'(x_{\text{max}}) \) are also taken to be small. The arbitrary normalization of \( \psi(x) \) allows these initial values to be chosen in a crude way. The relative sign of the derivatives at large \(|x|\) (determined e.g. by the parity of the wave function for even potentials) is also taken care by the renormalization of \( \psi(-)(x) \) when applying the matching condition. For an infinite well, the points \( x_{\text{min}}, x_{\text{max}} \) are the ones where the potential becomes infinite and \( \psi(-)(x_{\text{min}}) = \psi(+)(x_{\text{max}}) = 0 \).
3. Choose the initial value of the energy \( \epsilon \) and of the energy variation step \( \delta \epsilon \).
4. Calculate \( x_m \) from the initial value of the energy and the solution of \( v(x) = \epsilon \). Choose the solution that is at the left most side.\(^8\)
5. Evolve the equations \( \text{(10.24)} \) from \( x_{\text{min}} \) to \( x_m \) and obtain the solutions \( \psi(-)(x), \psi(-)'(x) \).
6. Evolve the equations \( \text{(10.24)} \) from \( x_{\text{max}} \) to \( x_m \) and obtain the solutions \( \psi(+)(x), \psi(+)'(x) \).
7. Renormalize \( \psi(-)(x) \rightarrow \psi(-)(x) \left( \psi(+)(x_m)/\psi(-)(x_m) \right) \), so that \( \psi(+)(x_m) = \psi(-)(x_m) \).
8. Compute the ratio \( f(\epsilon) \) of equation \( \text{(10.28)} \).

\(^{\text{If we are unlucky enough to pick a point where } \psi'(x_m) = 0, \text{ this criterion will fail.}}\)

\(^{\text{Note that this point changes when we vary } \epsilon}\)
• If $|f(\epsilon)| < \delta$ for appropriately chosen $\delta > 0$, the calculation ends. The result for the energy eigenvalue and eigenfunction is considered to be determined with adequate accuracy and we may proceed with the analysis of the results.

• If $f(\epsilon)$ changes sign it means that we have crossed the energy eigenvalue. Reverse the direction of search by taking $\delta \epsilon \rightarrow -\delta \epsilon / 2$.

• Change the energy $\epsilon \rightarrow \epsilon + \delta \epsilon$ and repeat by going back to the fourth step.

When we exit the above loop, the current wave function is a good approximation to the eigenfunction $\psi_n(x)$ corresponding to the eigenvalue $\epsilon_n$. We normalize the wave function according to equation (10.2) and we calculate the expectation values according to (10.9). It is also interesting to determine the number of nodes $n_0$ of the wave function which is related to $n$ by $n = n_0 + 1$.

Our program needs to implement the Runge–Kutta algorithm. We use the routine RKSTEP (see page 209) which performs a 4th order Runge–Kutta step. Its code is copied to the file rk.f90.

The potential $v(x)$ is coded in the function $V(x)$. The boundary conditions are programmed in the subroutine boundary(xmin, xmax, psixmin, psipxmin, psixmax, psipxmax) which returns the values of $psixmin = \psi'(-)(xmin)$, $psipxmin = \psi'(-)'(xmin)$, $psixmax = \psi'(+)(xmax)$, $psipxmax = \psi'(+)'(xmax)$ to the calling program. These routines are put in a separate file for each potential that we want to study. The name of the file is related to the form of the potential, e.g. we choose schInfSq.f90 for the infinite potential well of (10.17). The same file contains the code for the functions $f1$, $f2$:

```fortran
!-----------------------------------------------------------
! file: schInfSq.f
!
! Functions used in RKSTEP routine. Here:
! f1 = psip(x) = psi(x)'
! f2 = psip(x)' = psi(x)''
!
! One has to set:
! 1. V(x), the potential
! 2. The boundary conditions for psi.psip at x=xmin and x=xmax
!
*The number of points $x$ for which $\psi(x) = 0$ and $x_{min} < x < x_{max}$. The relation $n = n_0 + 1$ sets $\epsilon_1$ to be the ground state for which $n_0 = 0$.\n```
We note that if the potential becomes infinite for $x < x_{\text{min}}$ and/or $x > x_{\text{max}}$, then this will be determined by the boundary conditions at $x_{\text{min}}$ and/or $x_{\text{max}}$.

The main program is in the file sch.f90. The code is listed below and it includes the function $\text{integrate}(\psi, dx, N_x)$ used for the normalization of the wave function. It performs a numerical integration of the square of a function whose values $\psi(i) \ i=1,\ldots,N_x$ are given at an odd number of $N_x$ equally spaced points by a distance $dx$ using Simpson’s

measure normalization:
int = int*dx/3.0*D0
final result:
integrate = int
end function integrate

!====================================================================
CHAPTER 10. SCHröDINGER EQUATION

The reproduction of the results of the previous section for the infinite potential well is left as an exercise. The compilation and running of the program can be done with the commands:

```plaintext
> gfortran sch.f90 schInfSq.f90 rk.f90 -o s
> ./s
# Enter energy, de, xmin, xmax, Nx
1 0.5 -1 1 2000
# ####################################################################
# Estart= 1.000  de= 0.5
# Nx= 2001  eps= 1.0E-006
# xmin= -1.000  xmax= 1.000  dx= 1.000E-003
# psi(xmin)= 0.000  psip(xmin)= 1.000
# psi(xmax)= 0.000  psip(xmax)= -1.000
# ####################################################################
# iter, energy, de, xm, logd:
# 1 1.0000  0.500  -0.601  -0.9748
# 2 1.5000  0.500  -0.601  -0.6412
# .......
# 30 2.4674  3.815E-6  -0.601  -1.0E-6
# 31 2.4674  2.7E-7  -0.601  -2.7E-7
Final result: E= 2.467401504516602  n= 1  norm = 1.5707965025
```

We set xmin = -1, xmax = 1, Nx = 2000 and ε = 1, δε = 0.5. The energy of the ground state is found to be ε1 = 2.4674015045166016. The wave function is stored in the file psi.dat and can be plotted with the gnuplot command:

```plaintext
gnuplot> plot "psi.dat" using 1:2 with lines
```

The functions computed during the iterations of the algorithm are stored in the file all.dat. The first column is the iteration number (here we have iter = 0, ... 31) and we can easily filter each one of them with the commands:

```plaintext
gnuplot> plot "$1==1" all.dat using 3:4 with lines
```

which reproduce figure 10.6.
10.4 Measurements

The action of an operator $\hat{A}(\hat{x}, \hat{p})$ on a state $|\psi\rangle$ can be easily calculated in the position representation by its action on the corresponding wave function $\psi(x)$. The action of the operators

$$\hat{x}\psi(x) = x\psi(x) \quad \hat{p}\psi(x) = -i \frac{\partial}{\partial x}\psi(x)$$  \hspace{1cm} (10.29)

yield

$$\hat{A}(\hat{x}, \hat{p})\psi(x) = \mathcal{A}(x, -i \frac{\partial}{\partial x})\psi(x).$$  \hspace{1cm} (10.30)

Using equation (10.9) we can calculate the expectation value $\langle A \rangle$ of the operator $\mathcal{A}$ when the system is at the state $|\psi\rangle$. Interesting examples are the observables “position” $x$, “position squared” $x^2$, “momentum” $p$, “momentum squared” $p^2$, “kinetic energy” $T$, “potential energy” $V$, “energy” or “Hamiltonian” $H = T + V$ whose expectation values are

---

Footnote: We do not consider ordering problems of operators formed by products of non-commuting operators, e.g. $xp^2$. 

---

Figure 10.6: The convergence of the solutions to the solution of Schrödinger’s equation for the ground state of the infinite potential well according to the discussion on page 424.
given by the relations

\[
\langle x \rangle = \int_{-\infty}^{+\infty} \psi^*(x) x \psi(x) \, dx
\]
\[
\langle x^2 \rangle = \int_{-\infty}^{+\infty} \psi^*(x) x^2 \psi(x) \, dx
\]
\[
\langle p \rangle = \int_{-\infty}^{+\infty} \psi^*(x) \left(-i \frac{\partial}{\partial x}\right) \psi(x) \, dx
\]
\[
\langle p^2 \rangle = \int_{-\infty}^{+\infty} \psi^*(x) \left(-\frac{\partial^2}{\partial x^2}\right) \psi(x) \, dx
\]
\[
\langle T \rangle = \frac{\hbar^2}{2mL^2} \int_{-\infty}^{+\infty} \psi^*(x) \left(-\frac{\partial^2}{\partial x^2}\right) \psi(x) \, dx
\]
\[
\langle V \rangle = \frac{\hbar^2}{2mL^2} \int_{-\infty}^{+\infty} \psi^*(x) v(x) \psi(x) \, dx
\]
\[
\langle H \rangle = \frac{\hbar^2}{2mL^2} \int_{-\infty}^{+\infty} \psi^*(x) \left(-\frac{\partial^2}{\partial x^2} + v(x)\right) \psi(x) \, dx . \quad (10.31)
\]

We remind the reader that we used the dimensionless \( x, p \) as well as equations (10.15) and (10.16). Especially interesting are the “uncertainties” \( \Delta x^2 = \langle x^2 \rangle - \langle x \rangle^2 \), \( \Delta p^2 = \langle p^2 \rangle - \langle p \rangle^2 \) that satisfy the inequality (“Heisenberg’s uncertainty relation”)

\[
\Delta x \cdot \Delta p \geq \frac{1}{2} . \quad (10.32)
\]

In the previous section we described how to calculate numerically the eigenfunctions of the Hamiltonian. If \( H \psi(x) = E \psi(x) \), we obtain that \( \langle H \rangle = (1/2mL^2)E \). Other operators need a numerical approximation for the calculation of their expectation values. If the values of the wave function are given at \( N \) equally spaced points \( x_1, x_2, \ldots, x_N \), then we obtain

\[
\frac{\partial \psi(x_i)}{\partial x} \approx \frac{\psi(x_{i+1}) - \psi(x_{i-1})}{2h} \quad (10.33)
\]

where \( h = x_{i+1} - x_i \) and

\[
\frac{\partial^2 \psi(x_i)}{\partial x^2} \approx \frac{\psi(x_{i+1}) - 2\psi(x_i) + \psi(x_{i-1})}{h^2} . \quad (10.34)
\]

Both equations entail an error of the order of \( \mathcal{O}(h^2) \). Special care should be taken at the endpoints of the interval \([x_1, x_N]\). As a first approach we
will use the naive approximations\(^1\)

\[
\frac{\partial \psi(x_1)}{\partial x} \approx \frac{\psi(x_2) - \psi(x_1)}{h} \\
\frac{\partial \psi(x_N)}{\partial x} \approx \frac{\psi(x_N) - \psi(x_{N-1})}{h}
\]  

(10.35)

and

\[
\frac{\partial^2 \psi(x_1)}{\partial x^2} \approx \frac{\psi(x_3) - 2\psi(x_2) + \psi(x_1)}{h^2} \\
\frac{\partial^2 \psi(x_N)}{\partial x^2} \approx \frac{\psi(x_N) - 2\psi(x_{N-1}) + \psi(x_{N-2})}{h^2}
\]  

(10.36)

The relevant program that calculates \(\langle x \rangle, \langle x^2 \rangle, \langle p \rangle, \langle p^2 \rangle, \Delta x, \Delta p\) can be found in the file `observables.f90` and is listed below:

```
program observables_expectation
  implicit none
  integer, parameter :: P=50000
  integer Nx, i
  real(8) :: xstep(P), psi(P), obs(P)
  real(8) :: xav, pav, x2av, p2av, Dx, Dp, DxDp, energy, h, norm

  !---------------------------------------------------------------
  ! File observables.f90
  ! Compile: gfortran observables.f90 -o o
  ! Usage: ./o <psi.dat>
  !
  ! Read in a file with a wavefunction in the format of psi.dat:
  ! # E= <energy> ....
  ! x1   psi(x1)
  ! x2   psi(x2)
  ! ...........
  !
  ! Outputs expectation values:
  ! normalization Energy <x> <p> <x^2> <p^2> Dx Dp DxDp
  ! where Dx = sqrt(\langle x^2 \rangle - \langle x \rangle^2) Dp = sqrt(\langle p^2 \rangle - \langle p \rangle^2)
  ! DxDp = Dx * Dp
  !
  !---------------------------------------------------------------
```

\(^1\)See the files `observables.f90`, `Derivatives.nb` of the accompanying software. There you can find formulas that have errors of \(O(h^2)\). In the examples discussed below, the influence of the \(O(h)\) error on the results is approximately at the fourth significant digit.
CHAPTER 10. SCHRODINGER EQUATION

The program needs to read in the wave function at the points $x_1, \ldots, x_{E_x}$ in the format produced by the program in 
\texttt{sch.f90}. The first line should have the energy written at the 3rd column, whereas from the 2nd line and on there should be two columns with the $(x_i, \psi(x_i))$ pairs. It is not necessary to have the wave function properly normalized, the program will take care of it. If this data is stored in a file \texttt{psi.dat}, then the program can be used by running the commands

\begin{verbatim}
> gfortran observables.f90 -o obs
> ./obs psi.dat
\end{verbatim}

The program prints the normalization constant of $\psi(x)$, the value of the energy $\langle x \rangle$, $\langle x^2 \rangle$, $\langle \frac{p}{i} \rangle$, $\Delta x$, $\Delta p$ and $\Delta x \cdot \Delta p$ to the stdout.

Some details about the program: In order to read in the data from the file \texttt{psi.dat} we use the functions \texttt{iargc()}, \texttt{getarg(n,string)}. The former returns the number of arguments of the command line and the latter stores the n-th argument to the CHARACTER variable \texttt{string}. Therefore, the statements

\begin{verbatim}
character(20) :: psifile, scratch
if( iargc() .ne. 1) stop 'Usage: o <filename>'
call getarg(1,psifile)
\end{verbatim}

stop the program if the command line does not have exactly one argument and store the first argument to the variable \texttt{file}.

The command

\begin{verbatim}
open(unit=11, file=psifile, status='OLD', err=100)
100 stop 'Cannot open file'
\end{verbatim}

opens a file which should already exist (\texttt{status='OLD'}), otherwise an error message is issued. The option \texttt{err}=100 transfers the control of the program to the statement labeled \texttt{'100'}. In the example shown above, the one read from the file. It is not calculated from the data.
the program stops and prints an error message 'Cannot open filename' to the stdout.

The commands

```fortran
NX = 1
DO WHILE (.TRUE.)
   READ(11,*,END=101) XSTEP(NX), PSI(NX)
   NX = NX+1
ENDDO !DO WHILE (.TRUE.)
101  CONTINUE
```

read the opened file line by line. The option end=101 at the statement READ(11,*,end=101) transfers the control of the program to the labeled statement with label 101 (i.e. outside the do loop) when we reach the end of file.

The rest of the commands are applications of equations (10.33), (10.34), (10.35) and (10.36) to the formulas (10.31) and the reader is asked to study them carefully. The program uses the function integrate in order to perform the necessary integrals.

### 10.5 The Anharmonic Oscillator - Again...

In the previous chapter we studied the quantum mechanical harmonic and anharmonic oscillator in the representation of the energy eigenstates of the harmonic oscillator $|n\rangle$. In this section we will revisit the problem by using the position representation. We will calculate the eigenfunctions $\psi_{n,\lambda}(x)$ that diagonalize the Hamiltonian (9.15), which are the solutions of the Schrödinger equation. By setting $L = \sqrt{\hbar/m\omega}$ in equation (10.13), equation (10.12) becomes

$$\psi''(x) = -(\epsilon - v(x))\psi(x),$$

(10.37)

where $v(x) = x^2 + 2\lambda x^4$. For $\lambda = 0$ we obtain the harmonic oscillator with

$$\psi_n(x) = \frac{1}{\sqrt{2^n n!\sqrt{\pi}}} e^{-x^2/2} H_n(x), \quad \epsilon_n = 2\left(n + \frac{1}{2}\right),$$

(10.38)

where $H_n(x)$ are the Hermite polynomials.

We start with the simple harmonic oscillator where the exact solution is known. The potential and the initial conditions are programmed in the file schHOC.f90. The changes that we need to make concern the functions $V(x)$, boundary(xmin, xmax, psixmin, psipxmin, psixmax, psipxmax):
The code omitted at the dots is identical to the one discussed in the previous section. The initial conditions are inspired by the asymptotic behavior of the solutions to Schrödinger's equation \[ \psi_n(x) \sim e^{-x^2/2}, \psi'_n(x) \sim -x\psi_n(x). \] You are encouraged to test the influence of other choices on the results. The results are depicted in figure 10.7, where, besides the qualitative agreement, their difference from the known values (10.38) is also shown. This difference turns out to be of the order of $10^{-11} - 10^{-7}$. The values of the energy $\epsilon_n$ for $n \leq 14$ are in agreement with (10.38) with relative accuracy better than $10^{-9}$.

Then we calculate the expectation values $\langle x \rangle$, $\langle x^2 \rangle$, $\langle p \rangle$, $\langle p^2 \rangle$, $\Delta x$ and $\Delta p$. These are easily calculated using equations (9.4) and (9.8). We see that $\langle x \rangle = \langle n | (a^\dagger + a) / \sqrt{2} | n \rangle = 0$, $\langle p \rangle = \langle n | i(a^\dagger - a) / \sqrt{2} | n \rangle = 0$, whereas

\[ \langle x^2 \rangle = \langle p^2 \rangle = \langle n | \frac{1}{2} (a^\dagger a + aa^\dagger) | n \rangle = \left( n + \frac{1}{2} \right). \] (10.39)

The program observables.f90 calculates $\langle x \rangle = 0$ with accuracy $\sim 10^{-6}$ and $\langle p \rangle = 0$ with accuracy $\sim 10^{-11}$. The expectation values $\langle x^2 \rangle$, $\langle p^2 \rangle$ are shown in table 10.2.

---

\[ ^{13}\text{In fact } \psi_n(x) \sim x^n e^{-x^2/2} \text{ which we neglect. This does not influence the results for the values of } n \text{ studied here. Examine if this is necessary for larger values of } n. \]
Next, the calculation is repeated for the anharmonic oscillator for $\lambda = 0.5, 2.0$. We copy the file `schHOC.f90` to `schUOC.f90` and change the potential in the function $V(x)$:

```fortran
!============================================================================!
! file: schUOC.f
! ............................
! potential:
! real(8) function V(x)
!  implicit none
! real(8) :: x, lambda
! lambda = 2.0d0
! V = x*x+2.0d0*lambda*x*x*x*x
end function V
! ............................
```

The wave functions are plotted in figure 10.8. We see that by increasing $\lambda$ the particle becomes more confined in space as expected. In table 10.3 we list the values of the energy $\epsilon_n$ for $n = 0, ..., 9$. By increasing $\lambda$, $\epsilon_n(\lambda)$ is increased. Table 10.4 lists the expectation values $\langle x^2 \rangle$, $\langle p^2 \rangle$ and $\Delta x \cdot \Delta p$ for
Table 10.2: The expectation values $\langle x^2 \rangle$, $\langle p^2 \rangle$ and the product $\Delta x \cdot \Delta p$ for the simple harmonic oscillator for the states $|n\rangle$, $n = 0, \ldots, 14$.

10.6 The Lennard–Jones Potential

The Lennard–Jones potential is a simple phenomenological model of the interaction between two neutral atoms in a diatomic molecule. This is given by

\[
V(x) = 4V_0 \left\{ \left( \frac{\sigma}{x} \right)^{12} - \left( \frac{\sigma}{x} \right)^6 \right\}.
\]  

(10.40)

Figure 10.8: The wave functions of the anharmonic oscillator \( \psi_{n,\lambda}(x) \) for \( n = 0, 1, 2, 3, 4, 5 \) and \( \lambda = 0.5, 2.0 \) compared to the respective ones of the simple harmonic oscillator. Increasing \( \lambda \) yields stronger confinement of the particle in space.

\end{tabular}
\end{center}

Table 10.4: The expectation values \( \mathit{\langle x^2 \rangle} \), \( \mathit{\langle p^2 \rangle} \) and the product \( \Delta x \cdot \Delta p \) for the anharmonic oscillator for the states \( \mathit{|n\rangle} \), \( \mathit{n = 0, \ldots, 9} \). Note the decrease of \( \Delta x = \sqrt{\mathit{\langle x^2 \rangle}} \) and the increase of \( \Delta p = \sqrt{\mathit{\langle p^2 \rangle}} \) with increasing \( \lambda \). The uncertainty product \( \Delta x \cdot \Delta p \) seems to take values close to the corresponding ones of the harmonic oscillator for both values of \( \lambda \). Compare the results in this table with the ones in table 9.1.

The repulsive term describes the Pauli interaction due to the overlapping of the electron orbitals, whereas the attractive term describes the Van der Waals force. The first one dominates at short distances and the latter at long distances. We choose \( \mathit{L = \sigma} \) in \textit{(10.13)} and define \( \mathit{v_0 = 2m\sigma^2V_0/\hbar^2} \). Equation \textit{(10.40)} becomes

\[ v(x) = 4v_0 \left\{ \left( \frac{1}{x} \right)^{12} - \left( \frac{1}{x} \right)^6 \right\}, \quad (10.41) \]

whereas the eigenvalues \( \epsilon_n \) are related to the energy values \( E_n \) by

\[ \epsilon_n = 4v_0 \left( \frac{E_n}{V_0} \right). \quad (10.42) \]

The plot of the potential is shown in figure \textit{10.5} for \( v_0 = 250 \). The minimum is located at \( \mathit{x_m = 2^{1/6} \approx 1.12246} \) and its value is \(-v_0\). The code for this potential is in the file \textit{schLJ.f90}. The necessary changes to the code discussed in the previous sections are listed below:

</table>

For the integration we choose \( v_0 = 250 \) and \( x_{\text{min}} = 0.7, 4 < x_{\text{max}} < 10 \). The results are plotted in figure 10.9. There are four bound states. The first two ones are quite confined within the potential well whereas the last ones begin to “spill” out of it. Table 10.5 lists the results. We observe that \( \langle p \rangle = 0 \) within the attained accuracy as expected for real, bound states.\(^{14}\)

\(^{14}\)For \( \psi(+\infty) = \psi(0) = 0 \) and \( \psi^*(x) = \psi(x) \) we have that \( i\langle p \rangle/\hbar = \int_{-\infty}^{+\infty} \psi(x)(d/dx)\psi(x) \, dx = -\int_{-\infty}^{+\infty} (d/dx)\psi(x)\psi(x) \, dx = 0 \).
Figure 10.9: The four bound states for the Lennard-Jones potential with $v_0 = 250$. The bold red line is the potential $v(x)/v_0$. We plot the energy levels $\epsilon_n/v_0$ and the corresponding wave functions.

10.7 Problems

10.1 Add the necessary code to the program in the file well.f90 so that the final wave function printed in the file psi.dat is properly normalized. The integral $\int_a^b \psi(x)\bar{\psi}(x) \, dx$ can be computed using the Simpson rule

$$\int_a^b f(x) \, dx = \left( h/3 \right) \left( f(x_0) + 4f(x_1) + 2f(x_2) + \ldots + 2f(x_{n-2}) + 4f(x_{n-1}) + f(x_n) \right)$$

The interval $[a, b]$ is discretized by $n$ points $x_0 = a, x_1, x_2, \ldots, x_n = b$ where $n$ is even. Each interval $[x_i, x_{i+1}]$ has width $h$.

10.2 Add the necessary code to the program in the file well.f90 in order to calculate the number of nodes (zeroes) of the wave function. Using this result, the program should print the level $n$ of the calculated wave function $\psi_n(x)$.
10.7. PROBLEMS

10.3 Calculate the wave functions of the energy eigenstates for the potential (10.27) with \( v_0 < 0 \). This is the problem of the (finite) potential well. Solve the problem for \( v_0 = -100 \) and \( a = 0.3 \). How many bound states do you find? Next study the influence of the wall on the solutions. Introduce a parameter \( b \) so that \( v(x \geq b) = +\infty \) and study the dependence of the solutions on \( b \). Take \( b = 0.35, 0.4, 0.5, 0.6, 0.8, 1.0, 1.5, 2.0, 2.5, 3.0 \) and compute the difference of the first two energy eigenvalues. Estimate the accuracy of the method. Next lower the value of \( |v_0| \) until there is no bound state. What is the relation between \( a \) and \( v_0 \) when this happens? Compare with the analytic result which you know from your quantum mechanics course.

Hint: For the largest values of \( b \), take \( \epsilon x > 1000 \). When convergence is not achieved decrease \( \epsilon \).
10.4 Set \( v_0 = 1000, 5000 \) to the double well potential. Observe the (almost) degenerate states and plot the wave functions \( \psi_{\pm,n} = (1/\sqrt{2})(\psi_n(x) \pm \psi_{n+1}(x)) \), where \( n \) is odd. Compare the results with the corresponding energy levels and eigenfunctions of the infinite square well. Increase \( v_0 \) to the point where you cannot solve the problem numerically.

Hint: For large \( v_0 \) the numerical effort is increased. For \(|x| < a\) the wave function is almost zero and it is hard to obtain the non trivial wave function for \( a < |x| < 1 \). As the accuracy deteriorates, you should increase \( \text{epsilon} \) in the program so that convergence is achieved relatively fast.

10.5 Repeat problems 3 and 4 using the program \texttt{sch.f90}. Compare the results.

10.6 Study the bound states in the potentials

\[
v(x) = \begin{cases} 
0 & a < |x| \\
-V_0 & b < |x| < a \\
-V_1 & |x| < b
\end{cases}
\]

for \( a = 1, b = 0.2, V_0 = 100, V_1 = 0, 50 \) and

\[
v(x) = \begin{cases} 
V_1 & x < 0 \\
-V_0 & 0 < x < a \\
0 & a < x
\end{cases}
\]

for \( a = 1, V_0 = 100, V_1 = +\infty, 10, 100 \) and

\[
v(x) = \begin{cases} 
V_1 & a < |x| \\
-V_0 & b < |x| < a \\
0 & c < |x| < b \\
-V_0 & |x| < c
\end{cases}
\]

for \( a = 1, b = 0.7, c = 0.6, 0.3, V_0 = 100, V_1 = +\infty, 10, 0 \). In each case calculate \( \langle x \rangle, \langle x^2 \rangle, \langle p \rangle, \langle p^2 \rangle, \Delta x, \Delta p, \Delta x \cdot \Delta p \).

10.7 Write a program that calculates the probability that a particle is found in an interval \([x_1, x_2]\) given the wave function calculated by the program in the file \texttt{sch.f90}. Apply your program on the results of the previous problem and calculate the intervals \([-x_1, x_1]\) where the probability to find the particle inside them is equal to \(1/3\).

10.8 Fill the tables 10.3 and 10.4 with the results for \( \lambda = 0.2, 0.7, 1.0, 1.3, 1.6, 2.5, 3.0 \) and plot each expectation value as a function of \( \lambda \).
10.9 A particle is under the influence of a potential
\[ V(x) = \frac{\hbar^2}{2m} \alpha^2 \lambda(\lambda - 1) \left\{ \frac{1}{2} - \frac{1}{\cosh^2(\alpha x)} \right\}. \]

The energy spectrum is given by
\[ E_n = \frac{\hbar^2}{2m} \alpha^2 \left\{ \frac{\lambda(\lambda - 1)}{2} - (\lambda - 1 - n)^2 \right\} \]
for the values of \( n = 0, 1, 2, \ldots \) for which \( E_n > V_{\text{min}} \). Calculate the energy levels \( \epsilon_n \) of the bound states numerically by setting \( L = 1/\alpha \) in equation (10.13) and \( \lambda = 4 \). Plot the potential \( v(x) \) and the corresponding eigenfunctions. Calculate the expectation values of the position and momentum, the uncertainties in position and momentum and their product. Repeat for \( \lambda = 2, 6, 8, 10 \).

10.10 Write a program that reads in a wavefunction and calculates the expectation value of the Hamiltonian
\[ \langle \hat{H} \rangle = \int_{-\infty}^{+\infty} \psi(x) \left( -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + V(x) \right) \psi(x) \, dx, \]
by assuming that \( \psi(x) \) is real. Calculate \( \psi_n(x) \) for the harmonic oscillator for \( n = 1, \ldots, 10 \) and show (numerically) that \( \langle \hat{H} \rangle_n = E_n \).

10.11 Consider a particle in the Morse potential
\[ V(x) = D_e \left\{ (1 - e^{-a(x-x_e)})^2 - 1 \right\}. \]
Calculate the energy spectrum of the bound states. Choose \( L = 1/\alpha, \) \( x = ar, x_e = ar_e, \lambda^2 = 2mD_e/a^2\hbar^2 \) and obtain
\[ v(x) = \lambda^2 \left( e^{-2(x-x_e)} - 2e^{-(x-x_e)} \right). \]
Compare your results with the known analytic solutions
\[ \epsilon_n = \left( \lambda - n - \frac{1}{2} \right)^2 \]
\[ \psi_n(z) = N_n z^{\lambda-n-1/2} e^{-z/2} L_n^{2\lambda-2n-1}(z) \]
where \( z = 2\lambda e^{-(x-x_e)}, N_n = n!/(2\lambda - 2n - 1)/(\Gamma(n+1)\Gamma(2\lambda-n)), \) and \( L_n^\nu(z) \) is a Laguerre polynomial given by \( L_n^\nu(z) = (z^n e^z/n!)(d^n/dz^n)(z^{\nu+n} e^{-z}) \)
The first of the \( \Gamma(n+\lambda)/(\Gamma(n+2)\Gamma(\alpha+n+2)) \)s \( F_1\). You can take \( \lambda = 4, x_e = 1 \) and calculate \( \langle x \rangle, \langle x^2 \rangle, \langle p \rangle, \langle p^2 \rangle, \Delta x, \Delta p, \Delta x \cdot \Delta p. \)
10.12 Calculate the wave functions of the eigenstates of the Hamiltonian for the anharmonic oscillator for \( \lambda = 2.0 \) and \( n = 0, \ldots, 15 \). Calculate the wavefunctions using the program `anharmonic.f90` of chapter 9 for \( N = 15, 40, 100 \) and compare the two results.

Hint: Write a program that calculates the energy eigenfunctions of the simple harmonic oscillator

\[
\psi_n(x) = \frac{1}{\sqrt{2^n n! \sqrt{\pi}}} e^{-x^2/2} H_n(x)
\]

where the Hermite polynomials satisfy the relations

\[
H_{n+1}(x) = 2xH_n(x) - 2nH_{n-1}(x), \quad H_0(x) = 1, \quad H_1(x) = 2x.
\]

The program `anharmonic.f90` calculates the eigenstates of the anharmonic oscillator

\[
|n\rangle = \sum_{m=0}^{N-1} H(m + 1, n + 1) |m\rangle
\]

by storing the coefficients of the linear expansion in the elements of the array \( H(N,N) \). The same relation holds for the corresponding wave functions \( \psi_{n,\lambda}(x), \psi_n(x) \). From \( \psi_n(x) \) and \( H(i,j) \) calculate \( \psi_{n,\lambda}(x) \) for \(-8 < x < 8\) and determine the accuracy achieved by the calculation for each \( N \). For which values of \( x \) do you obtain large discrepancies between your results? Remember that for large \( x \), the states of high energy contribute more than for small \( x \). Figure 10.10 can help you understanding this statement.
Chapter 11

The Random Walker

In this chapter we will study the typical path followed by a ... drunk when he decides to start walking from a given position. Because of his drunkenness, his steps are in random directions and uncorrelated. These are the basic properties of the models that we are going to study. These models are related to specific physical problems like the Brownian motion, the diffusion, the motion of impurities in a lattice, the large distance properties of macromolecules etc. In the physics of elementary particles random walks describe the propagation of free scalar particles and they most clearly arise in the Feynman path integral formulation of the euclidean quantum field theory. Random walks are precursors to the theory of random surfaces which is related to the theory of two dimensional “soft matter” membranes, two dimensional quantum gravity and string theory [44].

The geometry of a typical path of a simple random walk is not classical and this can be seen from two of its non classical properties. First, the average distance traveled by the random walker is proportional to the square root of the time traveled, i.e. the classical relation \( r = vt \) does not apply. Second, the geometry of the path of the random walker has fractal dimension which is larger than one\(^1\). Similar structures arise in the study of quantum field theories and random surfaces, where the non classical properties of a typical configuration can be described by appropriate generalizations of these concepts. For further study we refer to [7,43,44,45].

In order to simulate a stochastic system on the computer, it is necessary to use random number generators. In most of the cases, these are deterministic algorithms that generate a sequence of pseudorandom num-

\(^1\)More precisely, the Hausdorff dimension of the simple random walk is \( d_H = 2 \).
bers distributed according to a desired distribution. The heart of these algorithms generate numbers distributed uniformly from which we can generate any other complex distribution. In this chapter we will study simple random number generators and learn how to use high quality, research grade, portable, random number generators.

11.1 (Pseudo)Random Numbers

The production of pseudorandom numbers is at the heart of a Monte Carlo simulation. The algorithm used in their production is deterministic: The generator is put in an initial state and the sequence of pseudorandom numbers is produced during its “time evolution”. The next number in the sequence is determined from the current state of the generator and it is in this sense that the generator is deterministic. Same initial conditions result in exactly the same sequence of pseudorandom numbers. But the “time evolution” is chaotic and “neighboring” initial states result in very different, uncorrelated, sequences. The chaotic properties of the generators is the key to the pseudorandomness of the numbers in the sequence: the numbers in the sequence decorrelate exponentially fast with “time”. But this is also the weak point of the pseudorandom number generators. Bad generators introduce subtle correlations which produce systematic errors. Truly random numbers (useful in cryptography) can be generated by using special devices based on e.g. radioactive decay or atmospheric noise. Almost random numbers are produced by the special files /dev/random and /dev/urandom available on unix systems, which read bits from an entropy pool made up from several external sources (computer temperature, device noise etc).

Pseudorandom number generators, however, are the source of random numbers of choice when efficiency is important. The most popular generators are the modulo generators (D.H. Lehmer, 1951) because of their simplicity. Their state is determined by only one integer \( x_{i-1} \) from which the next one \( x_i \) is generated by the relation

\[
x_i = a \times x_{i-1} + c \pmod{m}
\]  

(11.1)

- We can’t define what a random process is, only what it isn’t. Outcomes which lack discernable patterns are assumed to be random. If there is no way to predict an event, we say it is random...Thus, there is no definition of what randomness is, only definitions of what it isn’t. See Chris Wetzel, “Can you behave randomly?”, http://faculty.rhodes.edu/wetzel/random/level23intro.html
- There are online services which provide such sequences like www.random.org, www.fourmilab.ch/hotbits/ and others.
for appropriately chosen values of \(a, c\) and \(m\). In the bibliography, there is a lot of discussion on the good and bad choices of \(a, c\) and \(m\), which depend on the programming language and whether we are on a 32–bit or 64–bit systems. For details see the chapter on random numbers in [8].

The value of the integer \(m\) determines the maximum period of the sequence. It is obvious that if the sequence encounters the same number after \(k\) steps, then the exact same sequence will be produced and \(k\) will be the period of the sequence. Since there are at most \(m\) different numbers, the period is at most equal to \(m\). For a bad choice of \(a, c\) and \(m\) the period will be much smaller. But \(m\) cannot be arbitrarily large since there is a maximum number of bits that computers use for the storage of integers. For 4-byte (32 bit) unsigned integers the maximum number is \(2^{32} - 1\), whereas for signed integers \(2^{31} - 1\). One can prove⁴ that a good choice of \(a, c\) and \(m\) results in a sequence which is a permutation \(\{\pi_1, \pi_2, \ldots, \pi_m\}\) of the numbers \(1, 2, \ldots, m\). This is good enough for simple applications that require fast random number generation but for serious calculations one has to carefully balance efficiency with quality. Good quality random generators are more complicated algorithms and their states are determined by more than one integer. If you need the source code for such generators you may look in the bibliography, like in e.g. [4], [5], [8], [47]. If portability is an issue, we recommend the RANLUX random number generator [47] or the Marsaglia, Zaman and Tsang generator. The Fortran code for RANLUX can also be found in the accompanying software, whereas the MZT generator can be found in Berg’s book/site [5].

In order to understand the use of random number generators, but also in order to get a feeling of the problems that may arise, we list the code of the two functions naiveran() and drandom(). The first one is obviously problematic and we will use it in order to study certain type of correlations that may exist in the generated sequences of random numbers. The second one is much better and can be used in non–trivial applications, like in the random walk generation or in the Ising model simulations studied in the following chapters.

The function naiveran() is a simple application of equation (11.1) with \(a = 1277\), \(c = 0\) and \(m = 2^{17}\):

```fortran
!===================================================
! File: naiveran.f90
! Program to demonstrate the usage of a modulo

⁴See Knuth [46].
CHAPTER 11. THE RANDOM WALKER

The function \texttt{drandom()} is also an application of the same equation, but now we set \(a = 7^5, c = 0\) and \(m = 2^{31} - 1\). This is the choice of Lewis, Goodman and Miller (1969) and provides a generator that passes many tests and, more importantly, it has been used countless of times successfully. One technical problem is that, when we multiply \(x_{i-1}\) by \(a\), we may obtain a number which is outside the range of 4-byte integers and this will result in an “integer overflow”. In order to have a fast and portable code, it is desirable to stay within the range of the \(2^{31} - 1\) positive, 32-bit (4 byte), signed integers. Schrage has proposed to use the relation

\[
(ax_{i-1}) \mod m = \begin{cases} 
    a(x_{i-1} \mod q) - r \lfloor \frac{x_{i-1}}{q} \rfloor & \text{if it is } \geq 0 \\
    a(x_{i-1} \mod q) - r \lfloor \frac{x_{i-1}}{q} \rfloor + m & \text{if it is } < 0
\end{cases}
\]

(11.2)

where \(m = aq + r, q = [m/a]\) and \(r = m \mod a\). One can show that if \(r < q\) and if \(0 < x_{i-1} < m - 1\), then \(0 \leq a(x_{i-1} \mod q) \leq m - 1, 0 \leq r[x_{i-1}/q] \leq m - 1\) and that (11.2) is valid. The period of the generator is \(2^{31} - 2 \approx 2 \times 10^9\). The proof of the above statements is left as an exercise to the reader.

---

```fortran
! generator with a bad choice of constants
! resulting in strong pair correlations between
! generated numbers
!=========================================================================
real(8) function naiveran()
  implicit none
  integer :: iran=13337
  common /naiveranpar/ iran
  integer , parameter :: m = 131072 ! equal to 2**17
  integer , parameter :: a = 1277

  iran = a*iran
  iran = MOD(iran,m)

  naiveran = iran/DBLE(m)
end function naiveran
```

The function \texttt{drandom()} is also an application of the same equation, but now we set \(a = 7^5, c = 0\) and \(m = 2^{31} - 1\). This is the choice of Lewis, Goodman and Miller (1969) and provides a generator that passes many tests and, more importantly, it has been used countless of times successfully. One technical problem is that, when we multiply \(x_{i-1}\) by \(a\), we may obtain a number which is outside the range of 4-byte integers and this will result in an “integer overflow”. In order to have a fast and portable code, it is desirable to stay within the range of the \(2^{31} - 1\) positive, 32-bit (4 byte), signed integers. Schrage has proposed to use the relation

\[
(ax_{i-1}) \mod m = \begin{cases} 
    a(x_{i-1} \mod q) - r \lfloor \frac{x_{i-1}}{q} \rfloor & \text{if it is } \geq 0 \\
    a(x_{i-1} \mod q) - r \lfloor \frac{x_{i-1}}{q} \rfloor + m & \text{if it is } < 0
\end{cases}
\]

(11.2)

where \(m = aq + r, q = [m/a]\) and \(r = m \mod a\). One can show that if \(r < q\) and if \(0 < x_{i-1} < m - 1\), then \(0 \leq a(x_{i-1} \mod q) \leq m - 1, 0 \leq r[x_{i-1}/q] \leq m - 1\) and that (11.2) is valid. The period of the generator is \(2^{31} - 2 \approx 2 \times 10^9\). The proof of the above statements is left as an exercise to the reader.

The line that checks the result produced by the generator is necessary in order to check for the number 0 which appears once in the sequence. This adds a 10–20% overhead, depending on the compiler. If you don’t care about that, you may remove the line. Note that the number seed is put in a common block so it can be accessed by other parts of the program.

Now we will write a program in order to test the problem of correlations in the sequence of numbers produced by naiveran(). The program will produce pairs of integers \((i, j)\), where \(0 \leq i, j < 10000\), which are subsequently mapped on the plane. This is done by taking the integer part of the numbers \(Lu\) with \(L = 10000\) and \(0 \leq u < 1\) is the random number produced by the generator:

program correlations2
The program can be found in the file correlations2ran.f90. In order to test \texttt{naiveran()} we compile with the command

\begin{verbatim}
> gfortran correlations2ran.f90 naiveran.f90 -o naiveran
\end{verbatim}

whereas in order to test \texttt{drandom()} we uncomment the print lines as follows

\begin{verbatim}
! print *,INT(L * naiveran()),INT(L * naiveran())
print *,INT(L * drandom()),INT(L * drandom())
\end{verbatim}

and recompile:

\begin{verbatim}
> gfortran correlations2ran.f90 drandom.f90 -o drandom
\end{verbatim}

These commands result in two executable files \texttt{naiveran} and \texttt{drandom}. In order to see the results we run the commands

\begin{verbatim}
> ./naiveran 100000 > naiveran.out
> ./drandom 100000 > drandom.out
> gnuplot
gnuplot> plot "naiveran.out" using 1:2 with dots
gnuplot> plot "drandom.out" using 1:2 with dots
\end{verbatim}
which produce $10^5$ points used in the plots in figures 11.1 and 11.2. In
the plot of figure 11.1, we see the pair correlations between the num-
bers produced by \texttt{naiveran()}. Figure 11.2 shows the points produced
by \texttt{drandom()}, and we can see that the correlations shown in figure 11.1
have vanished. The plot in figure 11.2 is qualitative, and a detailed,
quantitative, study of \texttt{drandom()} shows that the pairs $(u_i, u_{i+1})$ that it
produces, do not pass the \textit{$\chi^2$} test when we have more than $10^7$ points,
which is much less than the period of the generator. In order to avoid
such problems, there are many solutions that have been proposed and
the simplest among them “shuffle” the results so that the low order se-
rial correlations vanish. Such generators will be discussed in the next
section. The uniform distribution of the random numbers produced

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig11.1}
\caption{Pairs of pseudorandom numbers produced by the function \texttt{naiveran()}. The correlations among pairs of such numbers show in the distribution of such pairs on a clearly seen lattice.}
\end{figure}

can be examined graphically by constructing a histogram of the relative
frequency of their appearance. In order to construct the histograms we
use the script \texttt{histogram} which is written in the \texttt{awk} language\footnote{See the accompanying software in the Tools directory. Give the command \texttt{histogram -- -h} which prints short usage instructions. I hope you remember how to make the file \texttt{histogram} executable and put it in your path...} as shown
Figure 11.2: Pairs of pseudorandom numbers produced by the function \texttt{drandom()}. These points have a random distribution on the plane compared to those generated by \texttt{naiveran()}. 

below:

\begin{verbatim}
> histogram -v f=0.01 drandom.out > drandom.hst
> gnuplot
gnuplot> plot "drandom.hst" using 1:3 with histeps
> gnuplot> plot [:][0:] "drandom.hst" using 1:3 with histeps
\end{verbatim}

The command \texttt{histogram -v f=0.01} constructs a histogram of the data so that the bin width is \(1/0.01 = 100\). The reciprocal of the number following the option \texttt{-v f=0.01} defines the bin width. The histogram is saved in the file \texttt{drandom.out}.

The results are shown in figures 11.3 and 11.4. Next, we study the variance of the measurements, shown in figure 11.3. The variance is decreased with the size of the sample of the collected random numbers. This is seen in the histogram of figure 11.5. For a quantitative study of the dependence of the variance on the size \(n\) of the sample, we calculate
11.1. (PSEUDO)RANDOM NUMBERS

Figure 11.3: The relative frequency distribution of the pseudorandom numbers generated by \texttt{drandom()}. The distribution is uniform within \((0, 1)\) and we see the deviations from the average value.

the standard deviation

\[
\sigma = \sqrt{\frac{1}{n-1} \left( \frac{1}{n} \sum_{i=1}^{n} x_i^2 - \left( \frac{1}{n} \sum_{i=1}^{n} x_i \right)^2 \right)},
\]

(11.3)

where \(\{x_i\}\) is the sequence of random numbers. Figure 11.6 plots this relation. By fitting

\[
\ln \sigma \sim \frac{1}{2} \ln(n),
\]

(11.4)

to a straight line, we see that

\[
\sigma \sim \frac{1}{\sqrt{n}}.
\]

(11.5)

If we need to generate random numbers which are distributed according to the probability density \(f(x)\) we can use a sequence of uniformly distributed random numbers in the interval \((0, 1)\) as follows: Consider the cumulative distribution function

\[
0 \leq u \equiv F(x) = \int_{-\infty}^{x} f(x') \, dx' \leq 1,
\]

(11.6)
which is equal to the area under the curve \( f(x) \) in the interval \((-\infty, x] \) and it is equal to the probability \( P(x' < x) \). If \( u \) is uniformly distributed in the interval \((0, 1)\) then we have that \( P(u' < u) = u \). Therefore \( x = F^{-1}(u) \) is such that \( P(x' < x) = u = F(x) \) and follows the \( f(x) \) distribution. Therefore, if \( u_i \) form a sequence of uniformly distributed random numbers, then the numbers

\[
x_i = F^{-1}(u_i)
\]

(11.7)

form a sequence of random numbers distributed according to \( f(x) \).

Consider for example the Cauchy distribution

\[
f(x) = \frac{1}{\pi} \frac{c}{c^2 + x^2} \quad c > 0.
\]

(11.8)

Then

\[
F(x) = \int_{-\infty}^{x} f(x') \, dx' = \frac{1}{2} + \frac{1}{\pi} \tan^{-1} \left( \frac{x}{c} \right).
\]

(11.9)

According to the previous discussion, the random number generator is given by the equation

\[
x_i = c \tan \left( \pi u_i - \pi/2 \right)
\]

(11.10)
or equivalently (for a more efficient generation)

\[ x_i = c \tan(2\pi u_i) \]  

(11.11)

The generator of Gaussian random numbers is found in many applications. The Gaussian distribution is given by the probability density

\[ g(x) = \frac{1}{\sqrt{2\pi} \sigma} e^{-x^2/(2\sigma^2)} \]  

(11.12)

The cumulative distribution function is

\[ G(x) = \int_{-\infty}^{x} g(x') \, dx' = \frac{1}{2} + \frac{1}{2} \text{erf} \left( \frac{x}{\sqrt{2} \sigma} \right) \]  

(11.13)

where \( \text{erf}(x) = \int_{-\infty}^{x} \exp\{-x'^2\} \, dx' \) is the error function. The error function, as well as its inverse, can be calculated numerically, but this would result in a slow computation. A trick to make a more efficient calculation is to consider the probability density \( \rho(x, y) \) of two independent Gaussian random variables \( x \) and \( y \)

\[ \rho(x, y) \, dx \, dy = \frac{1}{\sqrt{2\pi} \sigma} e^{-x^2/(2\sigma^2)} \frac{1}{\sqrt{2\pi} \sigma} e^{-y^2/(2\sigma^2)} \, dx \, dy = \frac{1}{2\pi \sigma^2} e^{-r^2/(2\sigma^2)} \, r \, dr \, d\phi \]  

(11.14)
where $x = r \cos \phi$, $y = r \sin \phi$. Then we have that

$$u = G(r) = \int_{0}^{r} \int_{0}^{2\pi} dr \, d\phi \, \rho(r, \phi) = 1 - e^{-r^2/(2\sigma^2)}, \quad (11.15)$$

which, upon inversion, it gives

$$r = \sigma \sqrt{-2 \ln(1 - u)}. \quad (11.16)$$

Therefore it is sufficient to generate a sequence $\{u_i\}$ of uniformly distributed random numbers and take

$$r_i = \sigma \sqrt{-2 \ln(u_i)}, \quad (11.17)$$
$$\phi_i = 2\pi u_{i+1}, \quad (11.18)$$
$$x_i = r_i \cos \phi_i, \quad (11.19)$$
$$x_{i+1} = r_i \sin \phi_i. \quad (11.20)$$

The algorithm shown above gives a sequence of pseudorandom numbers $\{x_i\}$, which follow the Gaussian distribution\footnote{It can be shown that $x_i, x_{i+1}$ are statistically independent.}. The program for $\sigma = 1$ is listed below:
11.2. Using Pseudorandom Number Generators

The function \( \text{drandom}() \) is good enough for the problems studied in this book. However, in many demanding and high accuracy calculations, it is necessary to use higher quality random numbers and/or have the need of much longer periods. In this section we will discuss how to use two high quality, efficient and portable generators which are popular among many researchers.

The first one is an intrinsic procedure in the Fortran language, the
Figure 11.7: The distribution of pseudorandom numbers generated by \texttt{gaussran()} for $\sigma = 1$ and $\sigma = 2$. The histogram is superimposed to the plot of (11.12).

subroutine \texttt{RANDOM\_NUMBER}. The algorithm implemented is not universal and depends on the Fortran environment. For the gfortran compiler \texttt{RANDOM\_NUMBER} uses the “multiply-with-carry” algorithm of George Marsaglia in combination with a modulo and shift-register generator. The period is larger than $2^{123} \approx 10^{37}$. The state of the generator is determined by more than one numbers. In order to use it we should learn

- how to start from a new state
- how to save the current state
- how to restart from a previously saved state
- and, of course, how to obtain the random numbers.

Saving the current state of the generator is very important when we execute a job that is split in several parts (checkpointing). This is done very often on computer systems that set time limits for jobs or when our

\footnote{Read carefully the documentation of your compiler. For this reason, the number \texttt{NSEEDS} can be different among different implementations of Fortran.}
11.2. USING PSEUDORANDOM NUMBER GENERATORS

Jobs are so long (more than 8-10 hours) that it will be painful to lose the resources (time and money) spent for the calculation in case of a computer crash. If we want to restart the job from exactly the same state as it was before we stopped, we also need to restart the random number generator from the same state.

Starting from a new, fresh state is called seeding. The seeding of \texttt{RANDOM\_NUMBER} is done by an unspecified number of \texttt{NSEEDS} integers. In order to get this number, we should call the subroutine \texttt{RANDOM\_SEED(size = NSEEDS)} which returns the number of seeds \texttt{NSEEDS} when its argument is \texttt{size = NSEEDS}. Then we have to define the integer values of the array \texttt{seeds(NSEEDS)} and call again the routine \texttt{RANDOM\_SEED(PUT = seeds)} with the argument \texttt{PUT = seeds}, which will seed the generator from the seeds in \texttt{seeds}. In the code listed below we show how to seed the generator by using only one integer seed:

```fortran
integer :: NSEEDS
integer, allocatable :: seeds(:)
integer :: seed

seed = 47279823

! seed = 47279823 call RANDOM\_SEED(size = NSEEDS)
ALLOCATE(seeds(NSEEDS))
seeds = seed + 37 * (/ (i - 1, i = 1, NSEEDS) /)
call RANDOM\_SEED(PUT = seeds)
```

The last line uses the values stored in the array \texttt{seeds(1) ... seeds(NSEEDS)} in order to initialize \texttt{RANDOM\_NUMBER}. It is important to note that, using this method, the same seed will generate the same sequence of pseudorandom numbers.

Sometimes we need to initialize the random number generator from as a random initial state as possible, so that each time that we run our program, a different sequence of random numbers is generated. For Unix like systems, like the GNU/Linux system, we can use the two special files \texttt{/dev/random} and \texttt{/dev/urandom} in order to generate cryptographic-grade random numbers. These generate random bits from the current state of the computer and it is practically impossible to predict the obtained sequence of bits. It is preferable to use \texttt{/dev/urandom} because \texttt{/dev/random} ceases to work when there are no new random bits in its pool and waits until they are safely generated. The code that uses \texttt{/dev/urandom} for

---

*The line before sets \texttt{seeds(1)=seed, seeds(2)=seed+37, seeds(3)=seed+37*2, ...}*

*The \texttt{access='stream'} argument in open is a Fortran 2003 and above feature. Make sure that your compiler accepts it.*
seeding is

```fortran
open(unit=13, file='/dev/urandom', access='stream', &
    form='unformatted')
call RANDOM_SEED(size = NSEEDS)
ALLOCATE(seeds(NSEEDS))
read (13) seeds
close(13)
```

The special file /dev/urandom provides binary, non printable, data so it is necessary to open it with the unformatted option. For the same reason, the command read does not have a format instruction but only the unit number. It reads the number of bits necessary to fill the array seeds. If we need to work in an environment where the special file /dev/urandom is not available, it is possible to seed using the current time and the process number ID. The latter is necessary in case we start several processes in parallel and we need different seeds. Check the file seed.f90 in order to see how to do it\(^\text{10}\).

In order to save the current state of the random number generator use the subroutine RANDOM_SEED(GET = seeds) with argument GET = seeds. The call stores the necessary information in the array seeds. We can save the values of the array seeds in order to use them to restart the random number generator from exactly the same state. The necessary code is:

```fortran
integer :: NSEEDS
integer, allocatable :: seeds(:)

! call RANDOM_SEED(size = NSEEDS)
ALLOCATE(seeds(NSEEDS))
call RANDOM_SEED(GET = seeds)
open(unit=11, file='state
write(11,*)seeds
```

In order to restart the generator from a saved state, we read the values of the array seeds and call RANDOM_SEED(PUT = seeds) with argument PUT = seeds. The following code reads seeds from a file named state:

```fortran
open(unit=11, file='state
read(11,*)seeds
```

\(^{10}\)You can also use the operating system in order to pass random seeds to your program. Try the commands set x = `~/dev/urandom tr -dc ":digit:" | head -c9 | awk 'printf "%d",$1'` ; echo $x and set x = `perl -e 'srand();print int(100000000*rand());'` ; echo $x. Use the value of the variable x for a seed.
11.2. USING PSEUDORANDOM NUMBER GENERATORS

call RANDOM_SEED(PUT = seeds)

In order to generate random numbers, we can use a scalar variable and generate them one by one or we can use an array which RANDOM_NUMBER will fill with random numbers. The first method has a small overhead and in some cases we will prefer the second one. The code that applies the first method is

```
real(8) :: r
!
!
do icount = 1,10
  call RANDOM_NUMBER(r)
  print *,r
enddo
```

and the code that applies the second is

```
integer, parameter :: NR=20
real(8), dimension(NR) :: randoms
call RANDOM_NUMBER(randoms)
p
```

The code in the file `test_random_number.f90` implements all of the above tasks and we list it below:

```
program use_random_number
  implicit none
  integer :: NSEEDS
  integer, allocatable :: seeds(:)
  integer :: seed
  real(8) :: r
  integer, parameter :: NR=20
  real(8), dimension(NR) :: randoms
  integer(NR) :: icount
  integer :: i
!
!start from a new seed:
  seed = 47279823
!get number of seeds for generator:
  call RANDOM_SEED(size = NSEEDS)
  ALLOCATE(seeds(NSEEDS))
!fill in the rest of the seeds:
  seeds = seed + 37 * (/ (i - 1, i = 1, NSEEDS) /)
!initialize the generator from the arrays seeds:
  call RANDOM_SEED(PUT = seeds)
```
A very high quality, portable random number generator was proposed by Martin Lüscher [47], and a program that implements it is Ranlux. Besides the high quality random numbers and a period greater than $10^{171}$, a great advantage of RANLUX is that it will run in any Fortran environment. The code, which can also be found in the accompanying software, has been written by Fred James and you can download it in its original form from the links given in the bibliography [47]. The generator uses a subtract-with-borrow algorithm by Marsaglia and Zaman [49], which has a very large period but fails some of the statistical tests. Based on the chaotic properties of the algorithm, Lüscher attributed the problems to short time autocorrelations and proposed a solution in order to eliminate them.
11.2. USING PSEUDORANDOM NUMBER GENERATORS

In order to start RANLUX using a single seed, use the subroutine RLUXGO. The necessary code is:

```fortran
integer :: seed, ranlux_level
!
seed = 58266273
ranlux_level = 2
call RLUXGO(ranlux_level, seed, 0.0)
```

The value of the variable ranlux_level determines the quality of random numbers and it can take the values 1, 2, 3 or 4. Setting ranlux_level=2 is enough for the needs of this book and ranlux_level=3 is the default value. A larger value of ranlux_level requires more computational effort (see problem).

In order to save the current state of RANLUX, we need an integer array of size 25. A call to the subroutine RLUXUT saves the necessary information in this array. We can save this array in order to read it at a later time and start the sequence of random numbers from the same point. The necessary code is:

```fortran
integer, parameter :: NSEEDS = 25
integer, dimension(NSEEDS) :: seeds
!
open(unit=11, file='ranlux.seed')
call RLUXUT(seeds)
write(11,*) seeds
close(11)
```

In order to start RANLUX from a previously saved state we call the subroutine RLUXIN as follows:

```fortran
integer, parameter :: NSEEDS = 25
integer, dimension(NSEEDS) :: seeds
open(unit=11, file='ranlux.seed')
read(11,*) seeds
call RLUXIN(seeds)
```

We can generate random numbers one by one and store them in a scalar variable

```fortran
real(8) :: r
!
call ranlux(r, 1)
```
or generate many random numbers with one call and store them in a one dimensional array.

```fortran
integer parameter :: NR=20
real(8) dimension(NR) :: randoms
!
call ranlux(randoms,NR)
print *,randoms
```

where the parameter NR is set equal to the desired value. The program in the file `test_ranlux.f90` implements all of the above tasks and we list it below:

```fortran
program use_ranlux
  implicit none
  integer parameter :: NSEEDS = 25
  integer dimension(NSEEDS) :: seeds
  integer :: seed, ranlux_level
  integer(8) :: icount
  real(8) :: r
  integer parameter :: NR=20
  real(8), dimension(NR) :: randoms
!
  start from a new seed:
  seed        = 58266273
  ranlux_level = 2
  call RLUXG0(ranlux_level,seed,0,0)
!
  generate random numbers one by one:
  do icount = 1,10
    call ranlux(r,1)
    print *,r
  enddo
!
  generate random numbers in an array:
  call ranlux(randoms,NR)
  print '(1000G28.17)',randoms
!
  save state of ranlux:
  open(unit=11,file='ranlux.seed')
  call RLUXUT(seeds)
  write(11,'(5120)')seeds
  close(11)
!
  generate some randoms:
  call ranlux(randoms,NR)
```

11.3 Random Walks

Consider a particle which is located at one of the sites of a two dimensional square lattice. After equilibrating at this position, it can jump randomly to one of its nearest neighbor positions. There, it might need some time to equilibrate again before jumping to a new position. During this time, the momentum that it had at its arrival is lost, therefore the next jump is made without “memory” of the previous position where it came from. This process is repeated continuously. We are not interested in the mechanism that causes the jumping¹¹ and we seek a simple phenomenological description of the process.

Assume that the particle jumps in each direction with equal probability and that each jump occurs after the same time \( \tau \). The minimum distance between the lattice sites is \( a \) (lattice constant). The vector that describes the change of the position of the particle during the \( i \)-th jump is a random variable \( \vec{\xi}_i \) and it always has the same magnitude \( |\vec{\xi}_i| = a \). This means that, given the position \( \vec{r}_k \) of the particle at time \( t_k = k\tau \), its position \( \vec{r}_{k+1} \) at time \( t_{k+1} = (k + 1)\tau = t_k + \tau \) is

\[
\vec{r}_{k+1} = \vec{r}_k + \vec{\xi}_k,
\]

¹¹It could be e.g. thermally stimulated sound waves, the quantum tunneling effect etc.
where

\[ \vec{\xi}_k = \begin{cases} 
  a \vec{x} & \text{with probability } \frac{1}{4} \\
  -a \vec{x} & \text{with probability } \frac{1}{4} \\
  a \vec{y} & \text{with probability } \frac{1}{4} \\
  -a \vec{y} & \text{with probability } \frac{1}{4} 
\end{cases}. \] (11.22)

The vectors \( \vec{\xi}_i \) and \( \vec{\xi}_j \) are uncorrelated for \( i \neq j \) and we have that

\[ \langle \vec{\xi}_i \cdot \vec{\xi}_j \rangle = \langle \vec{\xi}_i \rangle \cdot \langle \vec{\xi}_j \rangle. \] (11.23)

The possible values of \( \vec{\xi}_i \) are equally probable, therefore we obtain

\[ \langle \vec{\xi}_i \rangle = \vec{0}. \] (11.24)

This is because the positive and negative terms in the sum performed in the calculation of \( \langle \vec{\xi}_i \rangle \) occur with the same frequency and they cancel each other. Therefore \( \langle \vec{\xi}_i \cdot \vec{\xi}_j \rangle = 0 \) for \( i \neq j \). Since the magnitude of the vectors \( |\vec{\xi}_i| = a \) is constant, we obtain

\[ \langle \vec{\xi}_i \cdot \vec{\xi}_j \rangle = a^2 \delta_{i,j}. \] (11.25)

The probability for a path \( C_N \) of length \( N \) to occur is \( z \)

\[ p(C_N) = \frac{1}{z^N}, \] (11.26)

where \( z = 4 \) is the number of nearest neighbors of a lattice site. This probability depends on the length of the path and not on its geometry. This can be easily seen using the obvious relation \( p(C_{N+1}) = \frac{1}{z} p(C_N) \), since there are exactly \( z \) equally probable cases. The partition function is

\[ Z_N = z^N, \] (11.27)

and it counts the number of different paths of length \( N \).

After time \( t = N \tau \) the particle is displaced from its original position by

\[ \vec{R} = \sum_{i=1}^{N} \vec{\xi}_i. \] (11.28)

\(^{12}\)I.e. after time \( t = N \tau \), not the physical length of the path formed by the links that the particle has crossed. We also count the jumps to sites that the particle has already visited.
11.3. RANDOM WALKS

The average value of the displacement vanishes

$$\langle \vec{R} \rangle = \sum_{i=1}^{N} \langle \vec{\xi}_i \rangle = \vec{0}. \quad (11.29)$$

The expectation value of the displacement squared is non zero

$$\langle R^2 \rangle = \langle \vec{R} \cdot \vec{R} \rangle = \sum_{i,j=1}^{N} \langle \vec{\xi}_i \cdot \vec{\xi}_j \rangle = a^2 \sum_{i,j=1}^{N} \delta_{i,j} = a^2 N. \quad (11.30)$$

The conclusion is that the random walker has been displaced from its original position rather slowly

$$R_{\text{rms}} = \sqrt{\langle R^2 \rangle} = a \sqrt{N} \propto \sqrt{t}. \quad (11.31)$$

For a particle with a non zero average velocity we expect that $R_{\text{rms}} \propto t$.

Equation (11.31) defines the critical exponent $\nu$

$$\langle R^2 \rangle \sim N^{2\nu}, \quad (11.32)$$

where $\sim$ means asymptotic behavior in the limit $N \to \infty$. For a classical walker $\nu = 1$, whereas for the random walker $\nu = \frac{1}{2}$.

The Random Walker (RW) model has several variations, like the Non Reversal Random Walker (NRRW) and the Self Avoiding Walk (SAW). The NRRW model is defined by excluding the vector pointing to the previous position of the walker and by selecting the remaining vectors $\vec{\xi}_i$ with equal probability. The SAW is a NRRW with the additional requirement that, when the walker ends in a previously visited position, the ... walking ends! Some models studied in the literature include, besides the infinite repulsive force, an attractive contribution to the total energy for every pair of points of the path that are nearest neighbors. In this case, each path is weighted with the corresponding Boltzmann weight according to equation (12.4).

For the NRRW, equation (11.32) is similar to that of the RW, i.e. $\nu = \frac{1}{2}$. Even though the paths differ microscopically, their long distance properties are the same. They are examples of models belonging to the same universality class according to the discussion in section 13.1.

This is not the case for the SAW. For this system we have that [50]

$$\langle R^2 \rangle_{\text{SAW}} \sim N^{2\nu}, \quad \nu = \frac{3}{4}, \quad (11.33)$$
therefore the typical paths in this model are longer than those of the RW. If we introduce a nearest neighbor attraction according to the previous discussion, then there is a critical temperature $\beta_c$ such that for $\beta < \beta_c$ we have similar behavior given by equation (11.33), whereas for $\beta > \beta_c$ the attractive interaction dominates, the paths collapse and we obtain $\nu = 1/3 < \nu_{\text{RW}}$. For $\beta = \beta_c$ we have that $\nu = \frac{1}{4}$. For more information we refer the reader to the book of Binder and Heermann [7].

In order to write a program that simulates the RW we apply the following algorithm:

1. Set the number of the random walks to be generated
2. Set the number of steps of each walk
3. Set the initial position of the walk
4. At each step on the walk, pick a random direction with equal probability
5. After the walk is completed, measure $\vec{R}$, $R^2$, etc
6. After all walks have been generated, compute the expectation values of the measured quantities and the statistical error of their measurement.

All we need to explain is how to program the choice of “random direction”. The program is in the file rw.f90

```
program random_walker
  implicit none
  integer , parameter :: Nwalk = 1000
  integer , parameter :: Nstep = 100000
  integer :: iwalk, istep
  real(8) :: x, y
  real(8) :: drandom
  integer :: seed
  common /randoms/ seed

  seed = 374676287
  open(unit=20, file = 'dataR')
  do iwalk = 1, Nwalk
    x = 0.0D0 ; y = 0.0D0
    open(unit=21, file = 'data')
    do istep = 1, Nstep
      ir = INT(drandom() * 4)
      select case(ir)
```
The length of the paths is \( N_{\text{step}} \) and the number of the generated paths is \( N_{\text{walk}} \). Their values are hard coded and a run using different values requires recompilation. The results are written to the files \textit{dataR} and \textit{data}. The square of the final displacement of the walker \( R^2 \) is written to \textit{dataR} and the coordinates \((x; y)\) of the points visited by the walker in each path is written to \textit{data}. In order to make the contents of the files available immediately, we empty the I/O buffers by a call to the subroutine \texttt{flush(unit)}. The file \textit{data} is truncated at the beginning of each path, therefore it contains the coordinates of the current path only.

Each path is made of \( N_{\text{step}} \) steps. The random vector \( \vec{\xi}_{\text{step}} \) is chosen and it is added in the current position \( \vec{r}_{\text{step}} = (x; y) \). The choice on \( \vec{\xi}_{\text{step}} \) is made in the line

\[
\texttt{ir = INT(dr\text{andom()\}*4)}
\]

where the variable \( \texttt{ir} = 0, 1, 2, 3 \) because the function \texttt{INT} returns the integer part of a real. The values of \( \texttt{ir} \) correspond to the four possible directions of \( \vec{\xi} \). We use the construct \texttt{select case(ir)} in order to move in the direction chosen by \( \texttt{ir} \). Depending on its value, the control of the program is transferred to the command that moves the walker to the corresponding direction.

Compiling and running the program can be done with the commands

\[
> \texttt{gfortran rw.f90 dr\text{andom.f90} -o rw}
\]

\[
> \texttt{.\!/rw}
\]
Because of the command call `sleep(2)`, the program temporarily halts execution for 2 seconds at the end of each generated path (you should remove this line at the production stage). This allows us to monitor the generated paths graphically. During the execution of the program, use `gnuplot` in order to plot the random walk which is currently stored in the file `data`:

```
gnuplot> plot "data" with lines
```

Repeat for as many times as you wish to see new random walks. The automation of this process is taken care in the script `eternal-rw`:

```
> ./rw &
> ./eternal-rw &
> killall rw eternal-rw gnuplot
```

The last command ends the execution of all programs.

Some typical paths are shown in figure 11.8. Figure 11.9 shows the results for the expectation value $\langle R^2 \rangle$ for $N = 10, \ldots, 100000$ which confirm equation (11.30) $\langle R^2 \rangle = N$. You can reproduce this figure as follows:
1.3. RANDOM WALKS

Figure 11.9: Numerical confirmation of the relation $\langle R^2 \rangle = N$ for $N = 10, \ldots, 100000$. The straight line is the fit of the data to the function $y = ax$ with $a = 0.9994(13)$.

1. Set the values of Nwalk and Nstep in the file rw.f90. Delete the commands call sleep(2) and write(21,*) x,y and compile the code.

2. Run the program and analyze the data in the file dataR:

```
> ./rw
> awk '{av+=$1}END{print av/NR}' dataR
```

Write the results in a file r2.dat in two columns with the length of the paths $N$ in the first column and with $\langle R^2 \rangle$ in the second. The command $\{av+=$1\}$ in the awk program adds the first column of each line of the file dataR to the variable av. After reading the whole file, the command END{print av/NR}, prints the variable av divided by the number of lines in the file (NR = “Number of Records”). This is a simple way for computing the mean of the first column of the file dataR.

---

The command av+=$1 is equivalent to av=av+$1.
3. Use a linear squares method in order to find the optimal line \( y = ax + b \) going through the points \((\ln N, \ln \langle R^2 \rangle)\). You can also use the \texttt{fit} command in \texttt{gnuplot} as follows:

\begin{verbatim}
  gnuplot> fit a*x+b "r2.dat" u (log($1)):(log($2)) via a,b
\end{verbatim}

4. Construct the plot with the command:

\begin{verbatim}
  gnuplot> plot a*x+b."r2.dat" u (log($1)):(log($2)) w e
\end{verbatim}

The obtained results are meaningless without their statistical errors. Since each measurement is statistically independent, the true expectation value is approached in the limit of infinite measurements with a speed proportional to \( \sim 1/\sqrt{M} \), where \( M \) is the number of measurements. For the same reason\(^{14}\), the statistical error is given by equation \( (11.3) \), e.g.

\[
\delta \langle R^2 \rangle = \sqrt{\frac{1}{M-1} \left( \frac{1}{M} \sum_{i=1}^{M} (R^2_i)^2 - \left( \frac{1}{M} \sum_{i=1}^{M} R^2_i \right)^2 \right)}. \tag{11.34}
\]

We can add the calculation of the error in the program in \texttt{rw.f90} or we can leave this task to external utilities. For example we can use the \texttt{awk} script, which is written in the file \texttt{average}:

\begin{verbatim}
#!/usr/bin/awk -f
{
  av += $1; # the sum of data
  er += $1*$1; # the sum of squares of data
}
END{
  av /= NR; # NR = "Number of Records" = number of lines
  er /= NR;
  # formula for error of uncorrelated measurements
  er = sqrt((er - av*av)/(NR-1));
  print av, "+/--", er;
}
\end{verbatim}

The contents of this file is an example of a script \textit{interpreted} by the \texttt{awk} program. The operating system knows which program to use for the

\(^{14}\)If there exist statistical correlations between measurements, they should be taken into consideration. This will be discussed in detail in the following chapters.
interpretation by reading the first line 

```bash
#!/bin/awk -f
```

where the first two characters of the program should be exactly 

```bash
#!
```

. For the commands to be interpreted and executed, one has to make the script executable using the command `chmod a+x average`. Then the command

```bash
> ./average dataR
```

executes the script using the `awk` interpreter. We remind to the reader that the commands between curly brackets `{ ... }` are executed by `awk` for every line of the file `dataR`. The commands between `END{ ... }` are executed after the last line of the file has been read. Therefore the lines

```bash
av += $1;  # the sum of data
er += $1*$1;  # the sum of squares of data
```

add the first column of the file `dataR` and its square to the variables `av` and `er` respectively. The commands

```bash
av /= NR;  # NR = "Number of Records" = number of lines
er /= NR;
```

are executed after the whole file `dataR` has been read and divide the variables `av` and `er` with the predefined variable `NR` which counts the total number of lines read so far. The last lines of the script compute the error according to equation (11.34) and print the final result. The shell script in the file `rw1-anal.csh` codes all of the above commands in a script. Read the comments in the file for usage instructions.

## 11.4 Problems

1. Reproduce the results shown in figure 11.6 and confirm the validity of equation (11.5).

2. Generate a sequence of pseudorandom numbers which follow a Gaussian distribution with standard deviation \( \sigma = \frac{1}{\sqrt{2}} \). Construct the plot of relative frequencies together with the plot of the probability density function.

---

You can also execute a set of commands before the file is read by putting them between `BEGIN{ ... }`
3. Generate a sequence of pseudorandom numbers which follow the Cauchy distribution with $c = 1$. Construct the plot of relative frequencies together with the plot of the probability density function.

4. Write a program that calculates the period of the function `drandom()`. Check whether the numbers 0 and 1 belong to the sequence.

5. Compute the CPU time cost of the random number generation as follows: If you have an executable file, e.g. `random`, run the `/usr/bin/time` command with `.random` as its argument:

```
> /usr/bin/time ./random
```

Upon exit of the command, the program `/usr/bin/time` prints the total CPU time in seconds to the stderr. Compute the time needed to generate $10^9$ random numbers using the function `drandom()` and the subroutines `random_number` and `ranlux`. For RANLUX, measure the CPU time for each value of `ranlux_level` from 1 to 4. How does this time depend on whether the random numbers are generated one by one or in groups of 1000 by calls to `random_number` and `ranlux` having as an argument an array of size 1000? How does the time change if the random numbers are generated in groups of 10000 instead? (Hint: see the file `performance_ran.f90`)

6. For each of the random number generators `drandom()`, `random_number` and `ranlux`, generate 10 random numbers. Then save the state of the generator in a file. Then generate 10 more random numbers. Read from the file the saved state of the generator and generate 10 random numbers. Check that the last two sequences of random numbers are identical.

7. Make the appropriate changes in the file `seed.f90` so that it can be used for seeding RANLUX. Do it in two different ways: (a) by generating one seed and use `RLUXGO` for the initialization. (b) By generating 25 seeds and use `RLUXIN` for the initialization.

8. Show that if the expectation values of the vectors $\langle \vec{\xi} \rangle = \vec{v}\tau$ then $\langle \vec{R} \rangle = \vec{v}\tau N$ and we obtain a linear relation between displacement–length of path. The quantity $v$ is the expectation value of the speed of the particle. Compute $\langle R^2 \rangle$ for large values of $N$.

9. Confirm the relations computed in the previous problem numerically. In your program, set the first line in (11.22) equal to 1/2.
11.4. PROBLEMS

and the rest equal to 1/6. Compute the expectation values \( \langle \xi_i \rangle_x \) and \( \langle \xi_i \rangle_y \) and use them to calculate the average speed of the particle. Check the validity of the relations \( \langle R^2 \rangle \sim N^\alpha \) and \( \langle R_x \rangle \sim N^{2\alpha_x} \), \( \langle R_y \rangle \sim N^{2\alpha_y} \). What is the relation between \( \alpha \), \( \alpha_x \), and \( \alpha_y \)?

10. Make the appropriate changes in the file \( \text{rw.f90} \) so that the user can enter the values \( N_{\text{walk}} \) and \( N_{\text{step}} \) interactively using the command line arguments. For example, if she wants to generate 100 random walks with \( N = 2000 \), she should run the command \( ./\text{rw} \ 100 \ 2000 \). You will need to use the Fortran intrinsic functions GETARG and IARGC. (Hint: Look in the file \( \text{rw1.f90} \))

11. We know that for the RW we have that \( \langle \vec{R} \rangle = \vec{0} \). Calculate \( \langle x \rangle \) and \( \langle y \rangle \) numerically for \( N = 100, 100000 \). Are they really equal to zero? Why? How does this depend on the number of measurements?

12. Compute the expectation value of the number of returns of the RW to his initial position as a function of \( N \). What happens as \( N \to \infty \)? Why?

13. Reproduce figure [11.9] for the RW.

14. Write a program that implements the NRRW and reproduce the results in figure [11.9] for the NRRW.

15. In the program \( \text{rw.f90} \) the RW’s position is determined by two \( \text{REAL}(8) \) variables \( x, y \). The next position is calculated by the statements \( x=x+1.0\text{D0}, \ y=y+1.0\text{D0} \). What are the limitations on the size of random walks that can be studied with this choice? What happens if one uses \( \text{REAL} \) variables \( x, y \) instead? Take into account the fact that \( \langle R^2 \rangle = N \).

16. Repeat the previous problem by using \( \text{INTEGER}(8) \) variables \( x, y \). The next position is calculated by the statements \( x=x+1, \ y=y+1 \). Discuss the pros and the cons of each choice.

17. Repeat the previous problems by using \( \text{INTEGER}(4) \) variables \( x, y \). Discuss the pros and the cons of each choice by considering also the running time of the program. Use the command \( /usr/bin/time \).

18. Write a straightforward code that implements the SAW. How big \( N \) can you simulate? Check whether the CPU time for computing a given number of random walks increases exponentially with \( N \).
Search the internet for the most efficient algorithm that simulates the SAW for large $N$. 
Chapter 12

Monte Carlo Simulations

In this chapter we review the basic principles of Monte Carlo simulations in statistical mechanics. In the introduction, we review some of the fundamental concepts of statistical physics. The reader should have a basic understanding of concepts like the canonical ensemble, the partition function, the entropy, the density of states and the quantitative description of fluctuations of thermodynamic quantities. For a more in depth discussion of these concepts, see [4, 43, 51, 52, 53, 54].

For most of the interesting systems, the partition function cannot be calculated analytically, and in such a case we may resort to a numerical computation. This is what is done most effectively using Monte Carlo simulations, which consist of collecting a statistical sample of states of the system with an appropriately chosen probability distribution. It is remarkable that, by collecting a sample which is a tiny fraction of the total number of states, we can perform an accurate calculation of its thermodynamic quantities. But this is no surprise: it happens in our labs all the time!

¹For example, for the $d = 2, L = 100$ Ising model, we have $2^{100 \times 100} = 2^{10000} \approx 10^{3010}$ states. A typical sample yielding a very accurate measurement consists of $\approx 10^7$ states, i.e. a fraction of $\approx 10^{-3003}$. This fraction becomes many orders of magnitude smaller for realistic complex systems studied in today’s supercomputers.

²For a gas formed by $10^{22}$ molecules which has volume equal to 1 lt in room temperature and atmospheric pressure, the average velocity of its molecules is $\approx 100 m/s$. This means that the typical de Broglie wavelength of the molecules is $\lambda \approx 10^{-10} m$. If we estimate that the volume occupied by each molecule is of order $\lambda^3$, then the number of states that each molecule can be is $\approx 10^{27}$. Therefore the system can be in $\approx (10^{27})^{10^{22}}$ different states. If we assume that on the average the molecules collide $10^9$ times per second, then we have $\approx 10^{31}$ changes of states per second. In order that the system visits all possible states, the time needed is $10^{10^{22}}$ times the age of the universe [4].

475
12.1 Statistical Physics

Statistical physics describes systems with a very large number of degrees of freedom $N$. For simple macroscopic systems $N \approx 10^{23} - 10^{44}$. For such systems, it is practically impossible to solve the microscopic equations that govern their dynamics. Even if we could, the solution would have had much more information than we need (and capable of analyzing!). It is enough, however, to know a small number of bulk properties of the system in order to have a useful description of it. E.g. it is enough to know the internal energy and magnetization of a magnet or the energy and density of a fluid instead of the detailed knowledge of the position, momentum, energy and angular momentum of each particle they are made of. These quantities provide a thermodynamic description of a system. Statistical physics makes an attempt to derive these quantities from the microscopic degrees of freedom and their dynamics given by the Hamiltonian of the system.

Consider a system which can be in a set of discrete states which belong to a countable set $\{\mu\}$. The energy spectrum of those states is assumed to consist of discrete values $E_0 < E_1 < \ldots < E_n < \ldots$. This system is in contact and interacts with a large heat reservoir which has temperature $\beta = 1/kT$. The contact with the reservoir results in random transitions which change the energy of the system. The system is described by the weights $w_\mu(t)$ which give the probability to find the system in a state $\mu$ at time $t$. These weights are the connection between the microscopic and statistical description of the system. When this system is in thermal equilibrium with the reservoir, its statistical properties are described by the, so called, canonical ensemble.

Let $R(\mu \rightarrow \nu)$ be the transition rates from the state $\mu \rightarrow \nu$, i.e.

$$R(\mu \rightarrow \nu)dt = \text{Transition probability } \mu \rightarrow \nu \text{ in time } dt, \quad (12.1)$$

which depend on the interaction between the system and the thermal reservoir. The master equation for the weights $w_\mu(t)$ is

$$\frac{dw_\mu(t)}{dt} = \sum_\nu \{w_\nu(t)R(\nu \rightarrow \mu) - w_\mu(t)R(\mu \rightarrow \nu)\}$$

$$\sum_\mu w_\mu(t) = 1. \quad (12.2)$$

---

1. $E_0$ is the ground state energy of the system.
2. An isolated system always has constant energy. Such a system is studied in the microcanonical ensemble.
The first of the above equations tells us that the change in \( w_\mu(t) \) is equal to the rate that the system comes into the state \( \mu \) from any other state \( \nu \), minus the rate of leaving the state \( \mu \). The second equation is a result of the probability interpretation of the weights \( w_\mu(t) \) and states that the probability of finding the system in any state is equal to 1 at all times.

The transition rates \( R(\mu \rightarrow \nu) \) are assumed to be time independent and then the above system of equations for \( w_\mu(t) \) is linear with real parameters. This, together with the constraint \( 0 \leq w_\mu(t) \leq 1 \), implies that in the large time limit, \( \frac{dw_\mu(t)}{dt} = 0 \) and the system reaches equilibrium. Then, the \( w_\mu(t) \) converge to finite numbers \( p_\mu \geq 0 \). These are the equilibrium occupation probabilities

\[
p_\mu = \lim_{t \to \infty} w_\mu(t), \quad \sum_\mu p_\mu = 1. \tag{12.3}
\]

For a system in thermodynamic equilibrium with a reservoir in temperature \( T \), with \( \beta = 1/kT \), the probabilities \( p_\mu \) follow the Boltzmann distribution (Gibbs 1902)

\[
p_\mu = \frac{1}{Z} e^{-\beta E_\mu}, \tag{12.4}
\]

and define the, so called, canonical ensemble. The parameter \( \beta \) will be frequently referred to as simply “the temperature” of the system, although, strictly speaking, it is the inverse of it. Its appearance in the exponential in equation (12.4), defines a characteristic energy scale of the system. The Boltzmann constant \( k \approx 1.38 \times 10^{-23}JK^{-1} \) is simply a conversion constant between units of energy.

The normalization \( Z \) in equation (12.4) is the so called partition function of the system. The condition \( \sum_\mu p_\mu = 1 \) implies

\[
Z(\beta) = \sum_\mu e^{-\beta E_\mu} \tag{12.5}
\]

The measurement of a physical quantity, or observable, of a thermodynamic system has a stochastic character. For systems with very large number of degrees of freedom \( N \), one is interested only in the average

---

5Note that equation (12.2) can be written in the form \( \frac{d w_\mu(t)}{dt} = \sum_\nu R_{\mu \nu} w_\nu(t) \), where the matrix \( R_{\mu \nu} \) has real, constant elements.

6It is not a fundamental constant of nature like \( c, h, G, \ldots \). Temperature is an energy scale and the fact that it is customary to measure it in degrees Kelvin or other, is a historical accident due to the ignorance of the microscopic origin of heat exchange at the times of the original formulation of thermodynamics.
value of such a quantity. This is because the probability of measuring the quantity to take a value significantly different from its average is ridiculously small. The average, or expectation value, $\langle O \rangle$ of a physical observable $O$ whose value in a state $\mu$ is $O_\mu$ is equal to

$$\langle O \rangle = \sum_\mu p_\mu O_\mu = \frac{1}{Z} \sum_\mu O_\mu e^{-\beta E_\mu}. \quad (12.6)$$

As we will see later, the standard deviation $\Delta O$ for a typical thermodynamic system is such that

$$\frac{\Delta O}{O} \sim \frac{1}{\sqrt{N}}, \quad (12.7)$$

which is quite small for macroscopic systems. In such cases, the fluctuations of the values of $O$ from its expectation value $\langle O \rangle$ can be neglected. The limit $N \to \infty$ is the so-called thermodynamic limit, and it is in this limit in which we are studying systems in statistical mechanics. Most systems in the lab are practically in this limit, but in the systems simulated on a computer we may be far from it. The state of the art is to invent methods which can be used to extrapolate the results from the study of the finite system to the thermodynamic limit efficiently.

Because of (12.5), the partition function encodes all the statistical information about the system. It is not just a simple function of one or more variables, but it counts all the states of the system with the correct weight. Its knowledge is equivalent to being able to compute any thermodynamic quantity like, for example, the expectation value of the energy $\langle E \rangle$ of the system:

$$U \equiv \langle E \rangle = \frac{1}{Z} \sum_\mu E_\mu e^{-\beta E_\mu} = -\frac{1}{Z} \sum_\mu \frac{\partial}{\partial \beta} e^{-\beta E_\mu} = -\frac{1}{Z} \frac{\partial}{\partial \beta} \sum_\mu e^{-\beta E_\mu}$$

$$= -\frac{1}{Z} \frac{\partial Z}{\partial \beta} = -\frac{\partial \ln Z}{\partial \beta}. \quad (12.8)$$

Similarly, one can calculate the specific heat from

$$C = \frac{\partial U}{\partial \beta} = \frac{\partial}{\partial \beta} \left( -\frac{1}{Z} \frac{\partial Z}{\partial \beta} \right) = -\frac{kT^2}{Z} \frac{\partial^2 Z}{\partial \beta^2} = k\beta^2 \frac{\partial^2 \ln Z}{\partial \beta^2}. \quad (12.9)$$

\(^{7}\)E.g. for $N \approx 10^{23}$ we have that $\Delta O/O \approx 10^{-11}$ and the measurements of $O$ fluctuate at the 11th significant digit of their value. This is usually much smaller than other experimental errors.

\(^{8}\)In thermodynamics, $\langle E \rangle$ corresponds to the internal energy $U$ of the system.
12.2 Entropy

The entropy $S$ of a thermodynamic system is defined by

$$ S = -\frac{\partial F}{\partial T}, \quad F = U - TS, $$ (12.10)

where $F$ is the free energy if the system. We will attempt to provide microscopic definitions that are consistent with the above equations.

We define the free energy from the relation

$$ e^{-\beta F} = Z \equiv \sum_{\mu} e^{-\beta E_\mu}, $$ (12.11)

or equivalently

$$ F = -\frac{1}{\beta} \ln Z. $$ (12.12)

Note that for $T \to 0$ the free energy becomes the ground state energy \(^9\). Indeed, as $\beta \to \infty$ only the lowest energy term in equation (12.11) survives. For this reason, equation (12.10) gives $\lim_{T \to 0} S = 0$, which is the third law of thermodynamics.

The definition (12.11) is consistent with (12.10) since

$$ U = -\frac{\partial \ln Z}{\partial \beta} = -\frac{\partial}{\partial \beta}(-\beta F) = F + \beta \frac{\partial F}{\partial \beta} = F - T \frac{\partial F}{\partial T} = F + TS. $$ (12.13)

The relation of the entropy $S$ to the microscopic degrees of freedom can be derived from equations (12.11) and (12.10):

$$ \frac{S}{k} = \frac{U - F}{kT} = \beta(U - F) = \beta \left( \sum_{\mu} p_\mu E_\mu + \frac{1}{\beta} \ln Z \right). $$ (12.14)

But

$$ p_\mu = \frac{e^{-\beta E_\mu}}{Z} \Rightarrow E_\mu = -\frac{1}{\beta}(\ln p_\mu + \ln Z), $$ (12.15)

therefore

$$ \frac{S}{k} = \beta \sum_{\mu} \left( -\frac{1}{\beta}(\ln p_\mu + \ln Z)p_\mu + \frac{1}{\beta} \ln Z \right) $$

$$ = -\sum_{\mu} p_\mu \ln p_\mu - \ln Z \sum_{\mu} p_\mu + \ln Z $$

$$ = -\sum_{\mu} p_\mu \ln p_\mu. $$ (12.16)

\(^9\)For strict equality it is necessary that the ground state is not degenerate as it happens in the case of spontaneous symmetry breaking.
Finally

\[ S = -k \sum_{\mu} p_{\mu} \ln p_{\mu}. \]  

(12.17)

Let’s analyze the above relation in some special cases. Consider a system \(^{10}\) where all possible states have the same energy. For such a system, using equation (12.17), we obtain that

\[ p_{\mu} = \frac{1}{g} = \text{const.} \Rightarrow S = k \ln g. \]  

(12.18)

Therefore, the entropy simply counts the number of states of the system. This is also the case in the microcanonical ensemble. Indeed, equation (12.18) is also valid for the distribution

\[ p_{\mu} = \begin{cases} \frac{1}{g(E)} & E_{\mu} = E \\ 0 & E_{\mu} \neq E \end{cases}, \]  

(12.19)

which can be considered to be equivalent to the microcanonical ensemble since it enforces \( E_{\mu} = E = \text{const.} \) Equation (12.19) can viewed as an approximation to a distribution sharply peaked at \( E \). In such a case, \( S \) counts, more or less, the number of states of the system with energy close to \( E \).

In general, the function \(^{11}\) \( g(E) \) is defined to be equal to the number of states with energy equal to \( E \). Then the probability \( p(E) \) to measure energy \( E \) in the canonical ensemble is

\[ p(E) = \langle \delta_{E,E_{\mu}} \rangle = \sum_{\mu} p_{\mu} \delta_{E,E_{\mu}} = \frac{1}{Z} \sum E^{-\beta E_{\mu}} \delta_{E,E_{\mu}} = \frac{1}{Z} e^{-\beta E} \sum \delta_{E,E_{\mu}}. \]  

(12.20)

Since \( \sum_{\mu} \delta_{E,E_{\mu}} = g(E) \), we obtain

\[ p(E) = \langle \delta_{E,E_{\mu}} \rangle = \frac{g(E) e^{-\beta E}}{Z}. \]  

(12.21)

For a generic system we have that

\[ g(E) \sim E^{\alpha N}, \]  

(12.22)

where \( N \) is the number of degrees of freedom of the system and \( \alpha \) is a constant. The qualitative behavior of the distribution (12.21) is shown in

\(^{10}\)E.g. the random walker, two dimensional quantum gravity without matter.

\(^{11}\)The notation \( \Omega(E) \) is also frequently used and it is referred to as the density of states.
Figure 12.1: The probability $p(E)$ as a result of the competition of the Boltzmann factor $e^{-\beta E}$ and the density of states $g(E) \sim E^{\alpha N}$. $E^*$ is the most probable value of the energy and $\Delta E$ is a measure of the energy fluctuations.

For such a system the most probable values of the energy are sharply peaked around a value $E^*$ and the deviation $\Delta E$ is a measure of the energy fluctuations. The ratio $\Delta E / E$ drops with $N$ as $1/\sqrt{N}$. Indeed, the function

$$\tilde{p}(E) = E^{\alpha N} e^{-\beta E} = e^{-\beta E - \alpha N \ln E}$$

has a maximum when

$$\left. \frac{\partial \ln \tilde{p}(E)}{\partial E} \right|_{E=E^*} = 0 \Rightarrow \left. \frac{\partial}{\partial E} (-\beta E + \alpha N \ln E) \right|_{E=E^*} = -\beta + \frac{\alpha N}{E^*} = 0$$

or

$$E^* = \frac{\alpha}{\beta} N .$$

As the temperature increases ($\beta$ decreases), $E^*$ shifts to larger values. $E^*$ is proportional to the system size. By Taylor expanding around $E^*$ we

$^{12}$\(\tilde{p}(E)\) is proportional to $p(E)$ for fixed $\beta$. It is only defined for convenience.
obtain
\[
\ln \tilde{p}(E) = \ln \tilde{p}(E^*) + (E - E^*) \frac{\partial \ln \tilde{p}(E)}{\partial E} \bigg|_{E=E^*} + \frac{1}{2} (E - E^*)^2 \frac{\partial^2 \ln \tilde{p}(E)}{\partial E^2} \bigg|_{E=E^*} + \ldots
\]
\[
= \ln \tilde{p}(E^*) + \frac{1}{2} (E - E^*)^2 \left( -\frac{\alpha N}{(E^*)^2} \right) + \ldots, \quad (12.26)
\]
where we used equation (12.24) and computed \( \frac{\partial^2 \ln \tilde{p}(E)}{\partial E^2} \bigg|_{E=E^*} \). Therefore
\[
p(E) \approx p(E^*) e^{-\frac{\alpha N (E-E^*)^2}{2 (E^*)^2}}, \quad (12.27)
\]
which is a Gaussian distribution with standard deviation
\[
\Delta E \sim \sqrt{\frac{(E^*)^2}{\alpha N}} = \sqrt{\frac{\alpha N}{\alpha N}} \sim \frac{\sqrt{N}}{\beta}. \quad (12.28)
\]
Therefore we confirm the relation (12.7)
\[
\Delta E \sim \frac{\sqrt{N}}{\beta} \sim \frac{1}{\sqrt{N}}. \quad (12.29)
\]

In the analysis above we assumed analyticity (Taylor expansion, equation (12.26)), which is not valid at a critical point of a phase transition in the thermodynamic limit.

Another important case where the above analysis becomes slightly more complicated is when the distribution \( p(E) \) has more than one equally probable maxima, separated by a large probability barrier as shown in figure 12.2, like when the system undergoes a first order phase transition. Such a transition occurs when ice turns into water or when a ferromagnet losess its permanent magnetization due to temperature increase past its Curie point. In such a case the two states, ice – water / ferromagnet – paramagnet, are equally probable and coexist. This is qualitatively depicted in figure 12.2.

12.3 Fluctuations

The stochastic behavior of every observable \( O \) is given by a distribution function \( p(O) \) which can be derived from the Boltzmann distribution

\[11\] When there are many local maxima, the absolute maximum dominates in the thermodynamic limit \( N \to \infty \).
12.3. FLUCTUATIONS

\[ \Delta E = p(E) - p_{\text{min}} \]

\[ p_{\text{max}} \]

Figure 12.2: Two peak structure in the distribution \( p(E) \) of the energy \( E \) for a system undergoing a first order phase transition. The two maxima correspond to two coexisting states (“ice”–“water”) and \( \Delta E / N \) is the latent heat. In the thermodynamic limit \( N \to \infty, R = p_{\text{min}} / p_{\text{max}} \) decreases like \( R \sim e^{-fA} \), where \( A \) is the minimal surface separating the two phases and \( f \) is the interface tension.

(12.4) Such a distribution is completely determined by its expectation value \( \langle O \rangle \) and all its higher order moments, i.e. the expectation values \( \langle (O - \langle O \rangle)^n \rangle, n = 1, 2, 3, \ldots \). The most commonly studied moment is the second moment \((n = 2)\)

\[ (\Delta O)^2 \equiv \langle (O - \langle O \rangle)^2 \rangle = \langle O^2 \rangle - \langle O \rangle^2. \tag{12.30} \]

For a distribution with a single maximum, \( \Delta O \) is a measure of the fluctuations of \( O \) away from its expectation value \( \langle O \rangle \). When \( O = E \) we obtain

\[ (\Delta E)^2 \equiv \langle (E - \langle E \rangle)^2 \rangle = \langle E^2 \rangle - \langle E \rangle^2, \tag{12.31} \]

and using the relations

\[ \langle E^2 \rangle = \frac{1}{Z} \sum_{\mu} E_{\mu}^2 e^{-\beta E_{\mu}} = \frac{1}{Z} \frac{\partial^2}{\partial \beta^2} \sum_{\mu} e^{-\beta E_{\mu}} = \frac{1}{Z} \frac{\partial^2 Z}{\partial \beta^2}, \tag{12.32} \]

and

\[ \langle E \rangle = \frac{1}{Z} \sum_{\mu} E_{\mu} e^{-\beta E_{\mu}} = -\frac{1}{Z} \frac{\partial}{\partial \beta} \sum_{\mu} e^{-\beta E_{\mu}} = -\frac{1}{Z} \frac{\partial Z}{\partial \beta}, \tag{12.33} \]
we obtain that

\[(\Delta E)^2 = \langle E^2 \rangle - \langle E \rangle^2 = \frac{1}{\partial^2} \frac{\partial^2 Z}{Z \partial^2} - \left( -\frac{1}{Z \partial \beta} \right)^2 = \frac{\partial^2 \ln Z}{\partial \beta^2}, \tag{12.34} \]

which, according to (12.9), is the specific heat

\[C = \frac{\partial \langle E \rangle}{\partial T} = k \beta^2 (\Delta E)^2. \tag{12.35} \]

This way we relate the specific heat of a system (a thermodynamic quantity) with the microscopic fluctuations of the energy.

This is true for every physical quantity which is linearly coupled to an external field (in the case of $E$, this role is played by $\beta$). For a magnetic system in a constant magnetic field $B$, such a quantity is the magnetization $M$. If $M_\mu$ is the magnetization of the system in the state $\mu$ and we assume that its direction is parallel to the direction of the magnetic field $\vec{B}$, then the Hamiltonian of the system is

\[H = E - BM, \tag{12.36} \]

and the partition function is

\[Z = \sum_\mu e^{-\beta E_\mu + \beta BM_\mu}. \tag{12.37} \]

“Linear coupling” signifies the presence of the linear term $BM$ in the Hamiltonian. The quantities $B$ and $M$ are called conjugate to each other. Other well known conjugate quantities are the pressure/volume ($P/V$) in a gas or the chemical potential/number of particles ($\mu/N$) in the grand canonical ensemble.

Because of this linear coupling we obtain

\[\langle M \rangle = \frac{1}{Z} \sum_\mu M_\mu e^{-\beta E_\mu + \beta BM_\mu} = \frac{1}{\beta Z} \frac{\partial Z}{\partial B} = - \frac{\partial F}{\partial B}, \tag{12.38} \]

which is analogous to (12.8). The equation corresponding to (12.34) is obtained from (12.30) for $\mathcal{O} = M$

\[(\Delta M)^2 \equiv \langle (M - \langle M \rangle)^2 \rangle = \langle M^2 \rangle - \langle M \rangle^2. \tag{12.39} \]

From (12.37) we obtain

\[\langle M^2 \rangle = \frac{1}{Z} \sum_\mu M^2_\mu e^{-\beta E_\mu + \beta BM_\mu} = \frac{1}{\beta^2 Z} \frac{\partial^2 Z}{\partial B^2}, \tag{12.40} \]
therefore
\[(\Delta M)^2 = \frac{1}{\beta^2} \left\{ \frac{1}{Z} \frac{\partial^2 Z}{\partial B^2} - \frac{1}{Z^2} \left( \frac{\partial Z}{\partial B} \right)^2 \right\} = \frac{1}{\beta^2} \frac{\partial^2 \ln Z}{\partial B^2} = \frac{1}{\beta} \frac{\partial \langle M \rangle}{\partial B} \right\}. \quad (12.41)\]

The magnetic susceptibility $\chi$ is defined by the equation
\[\chi = \frac{1}{N} \frac{\partial \langle M \rangle}{\partial B} = \frac{\beta}{N} (\langle M \rangle - \langle M \rangle^2) \right\}, \quad (12.42)\]
where we see its relation to the fluctuations of the magnetization. This analysis can be repeated in a similar way for every pair of conjugate quantities.

### 12.4 Correlation Functions

The correlation functions can be obtained in a similar manner when we consider external fields which are space dependent. For simplicity, consider a system defined on a discrete lattice, whose sites are mapped to natural numbers $i = 1, \ldots, N$. Then the magnetic field $B_i$ is a function of the position $i$ and interacts with the spin $s_i$ so that
\[H = E - \sum_i B_i s_i. \quad (12.43)\]

Then the magnetization per site $m_i \equiv s_i^I$ at position $i$ is
\[\langle s_i \rangle = \frac{1}{\beta} \frac{\partial \ln Z}{\partial B_i}. \quad (12.44)\]

The connected two point correlation function is defined by
\[G_c^{(2)}(i, j) = \langle (s_i - \langle s_i \rangle)(s_j - \langle s_j \rangle) \rangle = \langle s_i s_j \rangle - \langle s_i \rangle \langle s_j \rangle = \frac{1}{\beta^2} \frac{\partial^2 \ln Z}{\partial B_i \partial B_j}. \quad (12.45)\]

When the values of $s_i$ and $s_j$ are strongly correlated, i.e., they “vary together” in the random samples that we take, the function (12.45) takes on large positive values. When the values of $s_i$ and $s_j$ are not at all correlated with each other, the terms $(s_i - \langle s_i \rangle)(s_j - \langle s_j \rangle)$ in the sum over $\mu$ in the expectation value $\langle (s_i - \langle s_i \rangle)(s_j - \langle s_j \rangle) \rangle$ cancel each other and $G_c^{(2)}(i, j)$ is zero.\(^1^4\)

\(^1^4\)Actually the two quantities are proportional to each other, but for simplicity we set the proportionality constant equal to 1.

\(^1^5\)There is also the possibility (not occurring in our discussion) that $s_i$ and $s_j$ are strongly anti-correlated in which case $G_c^{(2)}(i, j)$ is negative.
The function $G_c^{(2)}(i, j)$ takes its maximum value $\langle (s_i - \langle s_i \rangle)^2 \rangle$ for $i = j$. Then it falls off quite fast. For a generic system

$$G_c^{(2)}(i, j) \sim e^{-|x_{ij}|/\xi}, \quad (12.46)$$

where $|x_{ij}|$ is the distance between the points $i$ and $j$. The correlation length $\xi$ is a characteristic length scale of the system which is a measure of the distance where there is a measurable correlation between the magnetic moments of two lattice sites. It depends on the parameters that define the system $\xi = \xi(\beta, B, N, \ldots)$. It is important to stress that it is a length scale that arises dynamically. In contrast, length scales like the size of the system $L$ or the lattice constant $a$ are parameters of the system which don’t depend on the dynamics. In most of the cases, $\xi$ is of the order of a few lattice constants $a$ and such a system does not exhibit correlations at macroscopic scales (i.e. of the order of $L$).

Interesting physics arises when $\xi \to \infty$. This can happen by fine tuning the parameters on which $\xi$ depends on to their critical values. For example, in the neighborhood of a continuous phase transition, the exponential falloff in (12.46) vanishes and $G_c^{(2)}(i, j)$ falls off like a power (see figure 12.3)

$$G_c^{(2)}(i, j) \sim \frac{1}{|x_{ij}|^{d-2+v}}, \quad (12.47)$$

---

Footnote: I.e. not of first order.
where \( d \) is the number of dimensions of space and \( \eta \) a critical exponent. As we approach the critical point\(^\text{17}\), correlations extend to distances \( |x_{ij}| \gg a \). Then the system is not sensitive to the short distance details of the lattice and its dynamics are very well approximated by continuum space dynamics. Then we say that we obtain the continuum limit of a theory which is microscopically defined on a lattice. Since the microscopic details become irrelevant, a whole class of theories with different microscopic definitions\(^\text{18}\) have the same continuum limit. This phenomenon is called universality and plays a central role in statistical physics and quantum field theories.

## 12.5 Sampling

Our main goal is to calculate the expectation value \( \langle \mathcal{O} \rangle \),

\[
\langle \mathcal{O} \rangle = \sum_{\mu} p_\mu \mathcal{O}_\mu = \frac{\sum_\mu \mathcal{O}_\mu \exp(-\beta E_\mu)}{\sum_\mu \exp(-\beta E_\mu)}, \tag{12.48}
\]

of a physical quantity, or observable, \( \mathcal{O} \) of a statistical system in the canonical ensemble approximately. For this reason we construct a sample of \( M \) states \( \{\mu_1, \mu_2, \ldots, \mu_M\} \) which are distributed according to a chosen probability distribution \( P_\mu \). We define the estimator \( \mathcal{O}_M \) of \( \langle \mathcal{O} \rangle \) to be

\[
\mathcal{O}_M = \frac{\sum_{i=1}^M \mathcal{O}_{\mu_i} P_{\mu_i}^{-1} \exp(-\beta E_{\mu_i})}{\sum_{i=1}^M P_{\mu_i}^{-1} \exp(-\beta E_{\mu_i})}. \tag{12.49}
\]

The above equation is easily understood since, for a large enough sample, \( P_{\mu_i} \approx \text{“Frequency of finding } \mu_i \text{ in the sample”} \), and we expect that

\[
\langle \mathcal{O} \rangle = \lim_{M \to \infty} \mathcal{O}_M. \tag{12.50}
\]

Our goal is to find an appropriate \( P_\mu \) so that the convergence of (12.50) is as fast as possible. Consider the following cases:

### 12.5.1 Simple Sampling

We choose \( P_\mu = \text{const.} \), and equation (12.49) becomes

\[
\mathcal{O}_M = \frac{\sum_{i=1}^M \mathcal{O}_{\mu_i} \exp(-\beta E_{\mu_i})}{\sum_{i=1}^M \exp(-\beta E_{\mu_i})}. \tag{12.51}
\]

\(^{17}\)If we tune many parameters, this is a critical surface in the parameter space.

\(^{18}\)E.g. defined on square or triangular lattices, with nearest neighbor or next to nearest neighbor interactions.
The problem with this choice is the small overlap of the sample with the states that make the most important contributions to the sum in (12.48). As we have already mentioned in the introduction, the size of the sample in a Monte Carlo simulation is a minuscule fraction of the total number of states. Therefore, the probability of picking the ones that make important contributions to the sum in (12.48) is very small. Consider for example the case \( O = E \) in a generic model. According to equation (12.21) we have that

\[
\langle E \rangle = \sum_E E p(E),
\]

(12.52)

where \( p(E) \) is the probability of measuring energy \( E \) in the system. A qualitative plot of \( p(E) \) is shown in figure 12.1. From (12.25) and (12.28) we have that \( E^* \sim 1/\beta \) and \( \Delta E \sim 1/\beta \), therefore for \( \beta = 0 \) and \( \beta > 0 \) the qualitative behavior of the respective \( p(E) \) distributions is shown in figure 12.4. The distribution of the simple sampling corresponds to the case \( \beta = 0 \) in equation (12.4), since \( p_{\beta} = \text{const. in this case} \). In order to calculate the sum (12.52) with acceptable accuracy for \( \beta > 0 \) we have to obtain

\[\text{Figure 12.4: The distributions } p(E) \text{ for a generic model for temperatures } \beta = 0 \text{ and } \beta > 0. \text{ The two distributions have negligible overlap. In order that the } \beta = 0 \text{ distribution is as shown, we assume that the energy of all states is bounded and that the system has a finite number of degrees of freedom.}\]

\[\text{For these statements to be well defined, we assume that the energy of all states is bounded and that the system has a finite number of degrees of freedom. Otherwise consider the overlap for two temperatures } \beta_1 \gg \beta_2.\]
a good sample in the region where the product $E p_{\beta>0}(E)$ is relatively important. The probability of obtaining a state such that $E p_{\beta>0}(E)$ is non negligible is very small when we use the $p_{\beta=0}(E)$ distribution. This can be seen pictorially in figure 12.4.

Even though this method has this serious shortcoming, it could still be useful in some cases. We have already applied it in the study of random walks. Note that, by applying equation (12.51), we can use the same sample for calculating expectation values for all values of $\beta$.

### 12.5.2 Importance Sampling

From the previous discussion it has become clear that, for a large system, a very small fraction of the space of states makes a significant contribution to the calculation of $\langle O \rangle$. If we choose a sample with probability

$$P_{\mu} = p_{\mu} = \frac{e^{-\beta E_{\mu}}}{Z}, \quad (12.53)$$

then we expect to sample exactly within this region. Indeed, the estimator, given by equation (12.49), is calculated from

$$O_M = \frac{\sum_{i=1}^{M} O_{\mu_i} (e^{-\beta E_{\mu_i}})^{-1} e^{-\beta E_{\mu_i}}}{\sum_{i=1}^{M} (e^{-\beta E_{\mu_i}})^{-1} e^{-\beta E_{\mu_i}}} = \frac{1}{M} \sum_{i=1}^{M} O_{\mu_i}. \quad (12.54)$$

Sampling this way is called *importance sampling*, and it is the method of choice in most Monte Carlo simulations. The sample depends on the temperature $\beta$ and the calculation of the expectation values (12.54) requires a new sample for each $\beta$. This extra effort, however, is much smaller than the one required in order to overcome the overlap problem discussed in the previous subsection.

### 12.6 Markov Processes

Sampling according to a desired probability distribution $P_{\mu}$ is not possible in a direct way. For example, if we attempt to construct a sample according to $P_{\mu} = \frac{e^{-\beta E_{\mu}}}{Z}$ by picking a state $\mu$ by chance and add it to the sample with probability $P_{\mu}$, then we have a very small probability to accept that state in the sample. Therefore, the difficulty of constructing the sample

---

\[^{20}\text{We can use the same sample for a range of temperatures by using the histogram method, see \[2].}\]
runs into the same overlap problem as in the case of simple sampling. For this reason we construct a Markov chain instead. The members of the sequence of the chain will be our sample. A Markov process, or a Markov chain, is a stochastic process which, given the system in a state $\mu$, puts the system in a new state $\nu$ in such a way that it has the Markov property, i.e. that it is memoryless. This means that a chain of states

$$\mu_1 \rightarrow \mu_2 \rightarrow \ldots \rightarrow \mu_M,$$

is constructed in such a way that the transition probabilities $P(\mu \rightarrow \nu)$ from the state $\mu$ to a new state $\nu$ satisfy the following requirements:

1. They are independent of “time”
2. They depend only on the states $\mu$ and $\nu$ and not on the path that the system has followed on order to get to the state $\mu$ (memorylessness)
3. The relation

$$\sum_{\nu} P(\mu \rightarrow \nu) = 1$$

holds. Beware, in most of the cases $P(\mu \rightarrow \nu) > 0$, i.e. the system has a nonzero probability to remain in the same state
4. For $M \rightarrow \infty$ the sample $\{\mu_i\}$ follows the $P_\mu$ distribution.

Then our sample will be $\{\mu_i\} \equiv \{\mu_1, \mu_2, \ldots, \mu_M\}$. We may imagine that this construction happens in “time” $i = 1, 2, \ldots, M$. In a Monte Carlo simulation we construct a sample from a Markov chain by appropriately choosing the transition probabilities $P(\mu \rightarrow \nu)$ so that the convergence 4. is fast.

Choosing the initial state $\mu_1$ can become a non trivial task. If it turns out not to be a typical state of the sample, then it could take a long “time” for the system to “equilibrate”, i.e. for the Markov process to start sampling states typical of the simulated temperature. The required time for this to happen is called the thermalization time which can become a serious part of our computational effort if we make a wrong choice of $\mu_1$ and/or $P(\mu \rightarrow \nu)$.

A necessary condition for the sample to converge to the desired distribution is for the process to be ergodic. This means that for every state $\mu$ it is possible to reach any other state $\nu$ in a finite number of steps. If this criterion is not satisfied and a significant part of phase space is not sampled, then sampling will fail. Usually, given a state $\mu$, the reachable states $\nu$ at the next step (i.e. the states for which $P(\mu \rightarrow \nu) > 0$) are
very few. Therefore the ergodicity of the algorithm considered must be checked carefully.

12.7 Detailed Balance Condition

Equation (12.2) tells us that, in order to find the system in equilibrium in the $p_\mu$ distribution, the transition probabilities should be such that

$$\sum_\nu p_\mu P(\mu \to \nu) = \sum_\mu p_\nu P(\nu \to \mu).$$

(12.57)

This means that the rate that the system comes into the state $\mu$ is equal to the rate in which it leaves $\mu$. From equation (12.56) we obtain

$$p_\mu = \sum_\mu p_\nu P(\nu \to \mu).$$

(12.58)

This condition is necessary but it is not sufficient (see section 2.2.3 in [4]). A sufficient, but not necessary, condition is the detailed balance condition. When the transition probabilities satisfy

$$p_\mu P(\mu \to \nu) = p_\nu P(\nu \to \mu),$$

(12.59)

then the system will equilibrate to $p_\mu$ after sufficiently long thermalization time. By summing both sides of (12.59), we obtain the equilibrium condition (12.57). For the canonical ensemble (12.4) the condition becomes

$$\frac{P(\mu \to \nu)}{P(\nu \to \mu)} = \frac{p_\nu}{p_\mu} = e^{-\beta(E_\nu - E_\mu)}.$$

(12.60)

One can show that if the transition probabilities satisfy the above conditions then the equilibrium distribution of the system will be the Boltzmann distribution (12.4). A program implementing a Monte Carlo simulation of a statistical system in the canonical ensemble consists of the following main steps:

²¹There exist algorithms which are non-ergodic but the non reachable states are of “measure zero” in the space of states. These algorithms are formally non ergodic, but they are ergodic from a practical point of view. On the contrary, there exist algorithms that are formally ergodic but there are large regions of phase space where the probability of getting there is very small. This puts “ergodic barriers” in the sampling which will lead to wrong results. A common example is sampling a system in the neighborhood of a first order phase transition where, for large systems, it is very hard to sample states in both phases.
1. Write a program that codes appropriately chosen transition probabilities $P(\mu \to \nu)$ that satisfy condition (12.60).

2. Choose an initial state $\mu_1$.

3. Let the system evolve until it thermalizes to the Boltzmann distribution (12.4) (thermalization).

4. Collect data for the observables $O$ and calculate the estimators $O_M$ from equation (12.54).

5. Stop when the desired accuracy in the calculation of $\langle O \rangle$ has been achieved.

Equation (12.60) has many solutions. For a given problem, we are looking for the most efficient one. Below we list some possible choices:

$$P(\mu \to \nu) = A \cdot e^{-\frac{1}{2}\beta(E_\nu-E_\mu)}, \quad (12.61)$$

$$P(\mu \to \nu) = A \cdot \frac{e^{-\beta(E_\nu-E_\mu)}}{1 + e^{-\beta(E_\nu-E_\mu)}}, \quad (12.62)$$

$$P(\mu \to \nu) = A \cdot \begin{cases} e^{-\beta(E_\nu-E_\mu)} & E_\nu - E_\mu > 0 \\ 1 & E_\nu - E_\mu \leq 0 \end{cases}, \quad (12.63)$$

for appropriately chosen states $\nu \neq \mu$ and

$$P(\mu \to \mu) = 1 - \sum \nu P(\mu \to \nu). \quad (12.64)$$

$P(\mu \to \nu') = 0$ for any other state $\nu'$. In order for (12.64) to be meaningful, the constant $A$ has to be chosen so that

$$\sum_{\nu \neq \mu} P(\mu \to \nu) < 1. \quad (12.65)$$

Equation (12.65) gives much freedom in the choice of transition probabilities. In most cases, we split $P(\mu \to \nu)$ in two independent parts

$$P(\mu \to \nu) = g(\mu \to \nu) A(\mu \to \nu). \quad (12.66)$$

The probability $g(\mu \to \nu)$ is the selection probability of the state $\nu$ when the system is in the state $\mu$. Therefore the first step in the algorithm is to select a state $\nu \neq \mu$ with probability $g(\mu \to \nu)$. 
The second step is to accept the change with probability $A(\mu \to \nu)$. If the answer is no, then the system remains in the state $\mu$. This way equation (12.64) is satisfied. The probabilities $A(\mu \to \nu)$ are called the acceptance ratios.

The art in the field is to device algorithms that give the maximum possible acceptance ratios for the new states $\nu$ and that the states $\nu$ are as much as possible statistically independent from the original state $\mu$. An ideal situation is to have $A(\mu \to \nu) = 1$ for all $\nu$ for which $g(\mu \to \nu) > 0$. As we will see in a following chapter, this is what happens in the case of the Wolff cluster algorithm.

### 12.8 Problems

1. Prove equation (12.18).
2. Prove equation (12.19).
3. Prove equation (12.45).
4. Show that equations (12.61)–(12.63) satisfy (12.60).
CHAPTER 12. MONTE CARLO SIMULATIONS
Chapter 13

Simulation of the $d = 2$ Ising Model

This chapter is an introduction to the basic Monte Carlo methods used in the simulations of the Ising model on a two dimensional rectangular lattice, but also in a wide spectrum of scientific applications. We will introduce the Metropolis algorithm, which is the most common algorithm used in Monte Carlo simulations. We will discuss the thermalization of the system and the effect of correlations between successive spin configurations generated during the simulation. The autocorrelation function and the time scale defined by it, the autocorrelation time, are measures of these autocorrelations and play a central role in the study of the statistical independence of our measurements. Beating autocorrelations is crucial in Monte Carlo simulations since they are the main obstacle for studying large systems, which in turn is essential for taking the thermodynamic limit without the systematic errors introduced by finite size effects. We will also introduce methods for the computation of statistical errors that take into account autocorrelations. The determination of statistical errors is of central importance in order to assess the quality of a measurement and predict the amount of resources needed for reaching a specific accuracy goal.

13.1 The Ising Model

The Ising model (1925) [55] has played an important role in the evolution of ideas in statistical physics and quantum field theory. In particular, the two dimensional model is complicated enough in order to possess nontrivial properties but simple enough in order to be able to
obtain an exact analytic solution. The zero magnetic field model has a 2nd order phase transition for a finite value of the temperature and we are able to compute critical exponents and study its continuum limit in detail. This gives us valuable information on the non analytic properties of a system undergoing a second order phase transition, the appearance of scaling, the renormalization group and universality. Using the exact solution of Onsager (1948) and others, we obtain exact results and compare them with those obtained via approximate methods, like Monte Carlo simulations, high and low temperature expansions, mean field theory etc. The result is also interesting from a physics point of view, since it is the simplest, phenomenologically interesting, model of a ferromagnetic material. Due to universality, the model describes also the liquid/vapor phase transition at the triple point. A well known textbook for a discussion of statistical mechanical models that can be solved exactly is the book by Baxter.

In order to define the model, consider a two dimensional square lattice like the one shown in figure 13.1. On each site or node of the lattice we have an “atom” or a “magnet” of spin $s_i$. The geometry is determined by the distance of the nearest neighbors, the lattice constant $a$, and the number of sites $N$. Each side consists of $L$ sites so that $N = L \times L = L^d$, where $d = 2$ is the dimension of space. The topology is determined by the way sites are connected with each other via links. Special care is given to the sites located on the sides of the lattice. We usually take periodic boundary conditions which is equivalent to identifying the opposite sides of the square by connecting their sites with a link. This is depicted in figure (13.1). Periodic boundary conditions endow the plane on which the lattice is defined with a toroidal topology. The system’s dynamics are determined by the spin–spin interaction. We take it to be short range and the simplest case considered here takes into account only nearest neighbor interactions. In the Ising model, spins have two possible values, “up” or “down” which we map to the numerical values $+1$ or $-1$. For the ferromagnetic model, each link is a “bond” whose energy is higher when the spins on each side of the link are pointing in the same direction and lower when they point in the opposite direction. This is depicted in figure 13.1. The system could also be immersed in a constant magnetic

\footnote{For a very nice proof of Onsager’s solution look at the book by T. Huang and the paper by C.N. Yang.}

\footnote{This is only a convention. We could have picked 0 and 1 or any other pair of labels. The choice of labels affects only the expression of the Hamiltonian and related observables.}

\footnote{The opposite is true for the antiferromagnetic model.}
13.1. THE ISING MODEL

Figure 13.1: The two dimensional square lattice whose sites $i = 1, \ldots, N$ are occupied by “atoms” or “magnets” with spin $s_i$. In this figure spins may have any orientation on the plane (XY model). The simplest models take into account only the nearest neighbor interactions $-J \vec{s}_i \cdot \vec{s}_j$, where $(ij)$ is a link of the lattice. We take periodic boundary conditions which result in a toroidal topology on the lattice where the horizontal and vertical sides of the lattice are identified. In the figure, identified sides have the same color and their respective sites are connected by a link.

field $B$ whose direction is parallel to the direction of the spins.

We are now ready to write the Hamiltonian and the partition function of the system. Consider a square lattice of $N$ lattice sites (or vertices) labeled by a number $i = 1, 2, \ldots, N$. The lattice has $N_l$ links (or bonds) among nearest neighbors. These are labeled by $\langle ij \rangle$, where $(i, j)$ is the pair of vertices on each side of the link. We identify the sides of the square like in figure [13.1]. Then, since two vertices are connected by one link and four links intersect at one vertex, we have that

$$2N_l = 4N \Rightarrow N_l = 2N.$$  \hfill (13.1)

At each vertex we place a spin $s_i = \pm 1$. The Hamiltonian of the system

\footnote{It is easy to see that each vertex is in a one to one correspondence with a pair of links, say the east and north bound ones.}
Figure 13.2: The Ising model spins take two possible values: “up” or “down” and the Hamiltonian of the system is the sum of contributions of the energy of all links (“bonds”) \( \langle ij \rangle \). The energy of each bond takes two values, \(+J\) for opposite or \(-J\) for same spins, where \( J > 0 \) for a ferromagnetic system. The system possesses a discrete \( Z_2 \) symmetry: The Hamiltonian is invariant when all \( s_i \to -s_i \).

is given by

\[
H = -J \sum_{\langle ij \rangle} s_i s_j - B \sum_i s_i .
\]  

(13.2)

The first term is the spin–spin interaction and for \( J > 0 \) the system is ferromagnetic. In this book, we consider only the \( J > 0 \) case. A link connecting same spins has energy \(-J\), whereas a link connecting opposite spins has energy \(+J\). The difference of the energy between the two states is \(2J\) and the spin-spin dynamics favor links connecting same spins. The minimum energy \( E_0 \) is obtained for the ground state, which is the unique \(^5\) state in which all spins point in the direction \(^6\) of \( B \). This is equal to

\[
E_0 = -JN_1 - BN = -(2J + B)N .
\]

(13.3)

The partition function is

\[
Z = \sum_{s_1=\pm 1} \sum_{s_2=\pm 1} \ldots \sum_{s_N=\pm 1} e^{-\beta H(\{s_i\})} \equiv \sum_{\{s_i\}} e^{\beta J \sum_{\langle ij \rangle} s_i s_j + \beta B \sum_i s_i} ,
\]

(13.4)

where \( \{s_i\} \equiv \{s_1, s_2, \ldots, s_N\} \) is a spin configuration of the system. The number of terms is equal to the number of configurations \( \{s_i\} \), which is

\(^5\)When \( B = 0 \) the system has an “up–down” \( Z_2 \) symmetry. This means that states connected by the transformation \( s_i \to -s_i \) for all \( i \) result in the same Hamiltonian. In this case we have two ground states and the system chooses one of them by spontaneously breaking the \( Z_2 \) symmetry.

\(^6\)The vacuum structure of the antiferromagnetic system \( J < 0 \) for \( B = 0 \) is much richer.
equal to $2^N$, i.e. it increases exponentially with $N$. For a humble $5 \times 5$ lattice we have $2^{25} \approx 3.4 \times 10^6$ terms.

The two dimensional Ising model for $B = 0$ has the interesting property that, for $\beta = \beta_c$, where

$$\beta_c = \frac{1}{2} \ln (1 + \sqrt{2}) \approx 0.4406867935 \ldots ,$$

(13.5)

it undergoes a phase transition between an ordered or low temperature phase where the system is magnetized ($\langle |M| \rangle > 0$) and a disordered or high temperature phase where the magnetization vanishes ($\langle |M| \rangle = 0$). The magnetization $\langle |M| \rangle$ distinguishes between the two phases and it is called the order parameter. The critical temperature $\beta_c$ is the Curie temperature. The phase transition is of second order, which is a special case of a continuous phase transition. For a continuous phase transition the order parameter is continuous at $\beta = \beta_c$, but it is non analytic. For a second order phase transition, its derivative is not continuous. This is qualitatively depicted in figure 13.1.

For $\beta \neq \beta_c$ the correlation function behaves like in equation (12.46) resulting in a finite correlation length $\xi(\beta)$. The correlation length diverges as we approach the critical temperature, and its asymptotic behavior is

---

7 In contrast, a first order phase transition is a transition where the order parameter itself is discontinuous.

8 We mean the correlation length in the thermodynamic limit, i.e. we take the large $N$ limit first.
totic behavior in this limit is given by the scaling relation
\begin{equation}
\xi(\beta) \equiv \xi(t) \sim |t|^{-\nu}, \quad t = \frac{\beta_c - \beta}{\beta_c}.
\end{equation}

Then the correlation function behaves according to
\begin{equation}
G_{x}^{(2)}(i,j) \sim \frac{1}{|x_{ij}|^\eta}.
\end{equation}

Scaling behavior is also found for the specific heat \(C\), the magnetization \(M \equiv \langle |M| \rangle\) and the magnetic susceptibility \(\chi\) according to the relations
\begin{align}
C & \sim |t|^{-\alpha} \quad (13.8) \\
M & \sim |t|^{\beta} \quad (13.9) \\
\chi & \sim |t|^{-\gamma}, \quad (13.10)
\end{align}

whereas the magnetization for \(t = 0\) and nonzero magnetic field \(B \neq 0\) behaves like
\begin{equation}
M \sim B^{-1/\delta}. \quad (13.11)
\end{equation}

The exponents in the above scaling relations are called critical exponents or scaling exponents. They take universal values, i.e. they don’t depend on the details of the lattice construction or of the interaction. A whole class of such models with different microscopic definitions have the exact same long distance behavior. The systems in the same universality class need to share the same symmetries and dimensionality of space and the fact that the interaction is of short range. In the particular model that we study, these exponents take the so called Onsager exponent values
\begin{equation}
\alpha = 0, \quad \beta = \frac{1}{8}, \quad \gamma = \frac{7}{4}, \quad \delta = 15, \quad \nu = 1, \quad \eta = \frac{1}{4}.
\end{equation}

Theses exponents determine the non analytic behavior of the corresponding functions in the thermodynamic limit. Non analyticity cannot arise in the finite \(N\) model. The partition function \((13.4)\) is a sum of a finite number of analytic terms, which of course result in an analytic function. The non analytic behavior manifests in the \(N \to \infty\) limit, where the finite \(N\) analytic functions converge to a non analytic one. The loss of analyticity is related to the appearance of long distance correlations.

\[\text{i.e. at distances larger than the (diverging) correlation length.}\]
between the spins and the scaling of the correlation length according to equation \((13.6)\).

The two phases, separated by the phase transition, are identified by the different values of an order parameter. Each phase is characterized by the appearance or the breaking of a symmetry. In the Ising model, the order parameter is the magnetization and the symmetry is the \(Z_2\) symmetry represented by the transformation \(s_i \rightarrow -s_i\). The magnetization is zero in the disordered, high temperature phase and non zero in the ordered, low temperature phase. This implies that the magnetization is a non analytic function of the temperature.\footnote{An analytic function which is zero in an arbitrarily small interval, it is - by Taylor expanding around a point in this interval - everywhere zero.}

*Universality* and *scale invariance* appear in the \(\xi \rightarrow \infty\) limit. In our case, this occurs by tuning only one parameter, the temperature, to its critical value. A unique, dynamical, length scale emerges from the correlation function, the correlation length \(\xi\). Scale invariance manifests when the correlation length becomes much larger than the microscopic length scale \(\sigma\) when \(\beta \rightarrow \beta_c\). In the critical region, all quantities which are functions of the distance become functions only of the ratio \(r/\xi\). Everything depends on the long wavelength fluctuations required by the symmetry of the order parameter and all models in the same universality class have the same long distance behavior. This way one can study only the simplest model within a universality class in order to deduce the large distance/long wavelength properties of all systems in the class.

### 13.2 Metropolis

Consider a square lattice with \(L\) sites on each side so that \(N = L \times L = \xi^2\) is the number of lattice sites (vertices) and \(N_l = 2N\) is the number of links (bonds) between the sites. The relation \(N_l = 2N\) holds because we choose helical boundary conditions as shown in figure \(13.6\). The choice of boundary conditions will be discussed later. On each site \(i\) we have one degree of freedom, the “spin” \(s_i\) which takes on two values \(\pm 1\). We consider the case of zero magnetic field \(B = 0\), therefore the Hamiltonian is given by \footnote{The constant \(J = 1\) by choosing appropriate units for the \(s_i\).}

\[
H = - \sum_{\langle ij \rangle} s_i s_j . \tag{13.13}
\]
The sum $\sum_{\langle ij \rangle}$ is a sum over the links $\langle ij \rangle$, corresponding to the pairs of sites $i, j$. Then $\sum_{\langle ij \rangle} = (1/2) \sum_{i=1}^{N} \sum_{j=1}^{N}$ since each bond is counted twice in the second sum. The partition function is

$$Z = \sum_{s_1=\pm 1} \sum_{s_2=\pm 1} \ldots \sum_{s_N=\pm 1} e^{-\beta H([s_i])} \equiv \sum_{\{s_i\}} e^{\beta \sum_{\langle ij \rangle} s_i s_j}. \quad (13.14)$$

Our goal is to collect a sample of states that is distributed according to the Boltzmann distribution \(^{12.4}\). This will be constructed via a Markov process according to the discussion in section \(^{12.6}\). Sampling is made according to \(^{12.53}\) and the expectation values are estimated from the sample using \(^{12.54}\). At each step the next state is chosen according to \(^{12.60}\), and for large enough sample, or “time steps”, the sample is approximately in the desired distribution.

Suppose that the system is in a state $\mu$. According to \(^{12.66}\), the probability that in the next step the system goes into the state $\nu$ is

$$P(\mu \rightarrow \nu) = g(\mu \rightarrow \nu) A(\mu \rightarrow \nu), \quad (13.15)$$

where $g(\mu \rightarrow \nu)$ is the selection probability of the state $\nu$ when the system is in the state $\mu$ and $A(\mu \rightarrow \nu)$ is the acceptance ratio, i.e. the probability that the system jumps into the new state. If the detailed balance condition \(^{12.60}\)

$$\frac{P(\mu \rightarrow \nu)}{P(\nu \rightarrow \mu)} = \frac{g(\mu \rightarrow \nu) A(\mu \rightarrow \nu)}{g(\nu \rightarrow \mu) A(\nu \rightarrow \mu)} = e^{-\beta(E_{\nu} - E_{\mu})} \quad (13.16)$$

is satisfied, then the distribution of the sample will converge to \(^{12.4}\) $p_{\mu} = e^{-\beta E_{\mu}}/Z$. In order that the system changes states often enough, the probabilities $P(\mu \rightarrow \nu)$ should be of order one and the differences in the energy $E_{\nu} - E_{\mu}$ should not be too large. This means that the product of the temperature with the energy difference should be a number of order one or less. One way to accomplish this is to consider states that differ by the value of the spin on only one site $s_i = \pm 1 \rightarrow s_i' = \mp 1$. Since the energy \(^{13.13}\) is a local quantity, the change in energy will be small. More specifically, if each site has $z = 4$ nearest neighbors, the change of the spin on site $i$ results in a change of sign for $z$ terms $s_i s_j$ in \(^{13.13}\). The change in the energy for each bond is $\pm 2$. If the state $\mu$ is given by $\{s_1, \ldots, s_i, \ldots, s_N\}$ and the state $\nu$ by $\{s_1, \ldots, s'_i, \ldots, s_N\}$ (i.e. all the spins are the same except the spin $s_i$ which changes sign), the energy difference will be

$$|\Delta E| \leq 2z \iff E_{\mu} - 2z \leq E_{\nu} \leq E_{\mu} + 2z. \quad (13.17)$$

\(^{12}\)The state $\mu$ is determined by a spin configuration $\{s_i\}_{i=1}^{N}$.
If the site \( i \) is randomly chosen then
\[
g(\mu \rightarrow \nu) = g(\nu \rightarrow \mu) = \begin{cases} \frac{1}{N} & (\mu, \nu) \text{ differ by one spin} \\ 0 & \text{otherwise} \end{cases} ,
\]
and the algorithm is ergodic. Then we have that
\[
\frac{A(\mu \rightarrow \nu)}{A(\nu \rightarrow \mu)} = e^{-\beta(E_\nu - E_\mu)} .
\]
(13.18)

A simple choice for satisfying this condition is
\[
A(\mu \rightarrow \nu) = A_0 \cdot e^{-\frac{\beta}{2}(E_\nu - E_\mu)} .
\]
(13.19)

In order to maximize the acceptance ratios we have to take \( A_0 = e^{-\beta z} \).
Remember that we should have \( A(\mu \rightarrow \nu) \leq 1 \) and \( |\Delta E| \leq 2z \). Therefore
\[
A(\mu \rightarrow \nu) = e^{-\frac{1}{2}\beta(E_\nu - E_\mu + 2z)} .
\]
(13.20)

Figure 13.4 depicts the dependence of \( A(\mu \rightarrow \nu) \) on the change in energy
\[
\Delta E
\]
for different values of \( \beta \). We observe that this probability is small even for zero energy change and we expect this method not to perform very well.

It is much more efficient to use the algorithm proposed by Nicolas Metropolis et. al. 1953 [59] which is given by
\[
A(\mu \rightarrow \nu) = \begin{cases} e^{-\beta(E_\nu - E_\mu)} & E_\nu - E_\mu > 0 \\ 1 & E_\nu - E_\mu \leq 0 \end{cases} .
\]
(13.21)

Figure 13.4: The acceptance ratio \( A(\mu \rightarrow \nu) \) for the two dimensional Ising model on a square lattice given by equation (13.21) (left) and the Metropolis algorithm (right) as a function of the change in energy \( \Delta E = E_\nu - E_\mu \). For the Metropolis algorithm the acceptance ratios are larger and the algorithm is expected to perform better.
According to this relation, when a change in the states lowers the energy, the change is always accepted. When it increases the energy, the change is accepted with a probability less than one. As we can see in figure 13.4, this process accepts new states much more frequently than the previous algorithm.

The Metropolis algorithm is very widely used. It is applicable to any system, it is simple and efficient. We note that the choice to change the spin only locally is not a restriction put by the metropolis algorithm. There exist efficient algorithms that make non local changes to the system’s configuration that (almost) conserve the Hamiltonian and, consequently, the acceptance ratios are satisfactorily large.

13.3 Implementation

The first step in designing a code is to define the data structure. The degrees of freedom are the spins $s_i = \pm 1$ which are defined on $N$ lattice sites. The most important part in designing the data structure in a lattice simulation is to define the neighboring relations among the lattice sites in the computer memory and this includes the implementation of the boundary conditions. A bad choice of boundary conditions will make the effect of the boundary on the results to be large and increase the finite size effects. This will affect the speed of convergence of the results to the thermodynamic limit, which is our final goal. The most popular choice is the toroidal or periodic boundary conditions. A small variation of these lead to the so called helical boundary conditions, which will be our choice because of their simplicity. Both choices share the fact that each site has the same number of nearest neighbors, which give the same local geometry everywhere on the lattice and minimize finite size effects due to the boundary. In contrast, if we choose fixed or free boundary conditions on the sides of the square lattice, the boundary sites have a smaller number of nearest neighbors than the ones inside the lattice.

One choice for mapping the lattice sites into the computer memory is to use their coordinates $(i, j)$, $i, j = 1, \ldots, L$. Each spin is stored in an array $s(L, L)$. For a site $s(i, j)$ the four nearest neighbors are $s(i \pm 1, j)$, $s(i, j \pm 1)$. The periodic boundary conditions are easily implemented by adding $\pm L$ to $i, j$ each time they become less than one or greater than $L$. This is shown in figures 13.5 and 13.30.

The elements of the array $s(L, L)$ are stored linearly into the com-

---

1\(^{\text{An example is the Hybrid Monte Carlo used in lattice QCD simulations.}}\)
13.3. **IMPLEMENTATION**

Figure 13.5: An \( L = 5 \) square lattice with periodic boundary conditions. The topology is toroidal.

Computer memory. The element \( s(i,j) \) is at a “distance” \((j-1)\times L + i\) array positions from \( s(1,1) \) and accessing its value involves an, invisible to the programmer, multiplication. Using helical boundary conditions this multiplication can be avoided. The positions of the lattice sites are now given by one number \( i = 1, \ldots, L^2 = N \), as shown in figures 13.6 and 13.31. The spins are stored in memory in a one dimensional array \( s(N) \) and the calculation of the nearest neighbors of a site \( s(i) \) is easily done by taking the spins \( s(i \pm 1) \) and \( s(i \pm L) \). The simplicity of the helical boundary conditions is based on the fact that, for the nearest neighbors of sites on the sides of the square, all we have to do is to make sure that the index \( i \) stays within the accepted range \( 1 \leq i \leq N \). This is easily done by adding or subtracting \( N \) when necessary. Therefore in a program that we want to calculate the four nearest neighbors \( nn \) of a site \( i \), all we have to do is:

\[
\begin{align*}
\text{nn} &= i + 1; \text{if (nn.gt.N) nn=nn-N} \\
\text{nn} &= i - 1; \text{if (nn.lt.1) nn=nn+N} \\
\text{nn} &= i + L; \text{if (nn.gt.N) nn=nn-N} \\
\text{nn} &= i - L; \text{if (nn.lt.1) nn=nn+N}
\end{align*}
\]

We will choose helical boundary conditions for their simplicity and effi-
Figure 13.6: An $L = 5$ square lattice with helical boundary conditions. The topology is toroidal.

The dynamics of the Monte Carlo evolution is determined by the initial state and the Metropolis algorithm. A good choice of initial configuration can be important in some cases. It could lead to fast or slow thermalization, or even to no thermalization at all. In the model that we study it will not play an important role, but we will discuss it because of its importance in the study of other systems. We may choose a “cold” ($\beta = +\infty$ - all spins aligned) or a “hot” ($\beta = 0$ - all spins are equal to $\pm 1$ with equal probability $1/2$) initial configuration. For large lattices, it is desirable to start in one of these states and then lower/increase the temperature in small steps. Each time that the temperature is changed, the spin configuration is saved and used in the next simulation.

Ergodicity and thermalization must be checked by performing independent simulations and verify that we obtain the same results. Simi-

---

\[14^{\text{On the bad side, helical boundary conditions introduce a small finite size effect due to the shift of lattice positions in neighboring copies of the lattice. If one has to study small lattices, especially in higher dimensions, the best choice is to use periodic boundary conditions. We are going to study large enough lattices that this finite size effect is negligible.}}

\[15^{\text{Different sequence of random numbers.}}\]
larly, independent simulations starting from different initial states must also be checked that yield the same results.

Consider each step in the Markov process defined by the Metropolis algorithm. Assume that the system is in the state \( \mu = \{s_1^\mu, \ldots, s_k^\mu, \ldots, s_N^\mu\} \) and consider the transition to a new state \( \nu = \{s_1^\nu, \ldots, s_k^\nu, \ldots, s_N^\nu\} \) which differs only by the value of the spin \( s_k^\nu = -s_k^\mu \) (spin flip), whereas all the other spins are the same: \( s_j^\nu = s_j^\mu \, \forall j \neq k \). The energy difference between the two states is

\[
E_\nu - E_\mu = \left( -\sum_{(ij)} s_i^\nu s_j^\nu \right) - \left( -\sum_{(ij)} s_i^\mu s_j^\mu \right)
\]

\[
= -\sum_{(ik)} s_i^\mu (s_k^\nu - s_k^\mu)
\]

\[
= 2\sum_{(ik)} s_i^\mu s_k^\mu
\]

\[
= 2s_k^\mu \left( \sum_{(ik)} s_i^\mu \right),
\]

where the second line is obtained after the cancellation of the common terms in the sums. In the third line we used the relation \( s_k^\nu - s_k^\mu = -2s_k^\mu \), which you can prove easily by examining the cases \( s_k^\mu = \pm 1 \) separately. The important property of this relation is that it is local since it depends only on the nearest neighbors. The calculation of the energy difference \( E_\nu - E_\mu \) is fast and is always a number of order one \(^{16}\).

The Metropolis condition is easily implemented. We calculate the sum in the parenthesis of the last line of equation (13.23) and obtain the energy difference \( E_\nu - E_\mu \). If the energy decreases, i.e. \( E_\nu - E_\mu \leq 0 \), the new state \( \nu \) is accepted and "we flip the spin". If the energy increases, i.e. \( E_\nu - E_\mu > 0 \), then the acceptance ratio is \( A(\mu \rightarrow \nu) = e^{-\beta(E_\nu - E_\mu)} < 1 \). In order to accept the new state with this probability we pick a random number uniformly distributed in \( 0 \leq x < 1 \). The probability that this number is \( x < A(\mu \rightarrow \nu) \) is equal to \( \int_A(x) \). Therefore if \( x \geq A(\mu \rightarrow \nu) \) the change is accepted. If \( x > A(\mu \rightarrow \nu) \) the change is rejected and the system remains in the same state \( \mu \).

A small technical remark is in order: The possible values of the sum \( \sum_{(ik)} s_i^\mu \) are \(-4, -2, 0, 2, 4\) and these are the only values that enter in the calculation of \( A(\mu \rightarrow \nu) \). Moreover, only the values that increase

---

\(^{16}\) An important fact is that it does not increase with the system size.

\(^{17}\) For the uniform distribution \( P(x < a) = a \).
the energy, i.e. 2,4 are of interest to us. Therefore we only need two values of \(A(\mu \rightarrow \nu)\), which depend only on the temperature. These can be calculated once and for all in the initialization phase of the program, stored in an array and avoid the repeated calculation of the exponential \(e^{-\beta(E_\nu - E_\mu)}\) which is expensive.

In our program we also need to implement the calculation of the observables that we want to measure. These are the energy \((13.13)\)

\[
E = -\sum_{\langle ij \rangle} s_i s_j, \tag{13.24}
\]

and the magnetization

\[
M = \left| \sum_i s_i \right|. \tag{13.25}
\]

Beware of the absolute value in the last equation! The Hamiltonian \(H\) has a \(Z_2\) symmetry because it is symmetric under reflection of all the spins. The probability of appearance of a state depends only on the value of \(H\), therefore two configurations with opposite spin are equally probable. But such configurations have opposite magnetization, therefore the average magnetization \(\langle \sum_i s_i \rangle\) will be zero due to this cancellation.

We can measure the energy and the magnetization in two ways. The first one is by updating their values each time a Metropolis step is accepted. This is easy and cheap since the difference in the sum in equations \((13.24)\) and \((13.25)\) depends only on the value of the spin \(s_k^\mu\) and its nearest neighbors. The energy difference is already calculated by \((13.23)\) whereas the difference in the magnetization in \((13.25)\) is given by

\[
\sum_i s_i^\nu - \sum_i s_i^\mu = s_k^\nu - s_k^\mu = -2s_k^\mu \tag{13.26}
\]

The second way is by calculating the full sums in \((13.24)\) and \((13.25)\) every time that we want to take a measurement. The optimal choice depends on how often one obtains a statistically independent measurement.\(^{19}\) If the average acceptance ratio is \(\bar{A}\), then the calculation of the magnetization using the first method requires \(AN\) additions per \(N\) Monte Carlo steps, whereas the second one requires \(N\) additions per measurement.

\(^{16}\)This does not show for very small temperatures in the simulation with the Metropolis algorithm. As we decrease the temperature \(\beta \gg \beta_c\), it takes many improbable steps to move from a state with \(\sum_i s_i = M_1\) to a state with \(\sum_i s_i = -M_1\). The Monte Carlo simulation consists of a finite number of steps, therefore we may obtain a non zero \(\langle \sum_i s_i \rangle\), an incorrect result.

\(^{18}\)This is given by the autocorrelation time, which will be discussed in detail later.
We use the normalization
\[
\langle e \rangle = \frac{1}{N_l} \langle E \rangle = \frac{1}{2N} \langle E \rangle ,
\]
which gives the energy per link. We have that \(-1 \leq e \leq +1\), where \(e = -1\) for the ground state in which all \(2N\) links have energy equal to \(-1\). The magnetization per site is
\[
\langle m \rangle = \frac{1}{N} \langle M \rangle .
\]
We have that \(0 \leq m \leq 1\), where \(m = 0\) for \(\beta = 0\) (perfect disorder) and \(m = 1\) for the ground state at \(\beta = \infty\) (perfect order). We call \(m\) the order parameter since its value determines the phase that the system is in.

The specific heat is given by the fluctuations of the energy
\[
c = \beta^2 N \langle (e - \langle e \rangle)^2 \rangle = \beta^2 N \langle (e^2) - \langle e \rangle^2 \rangle ,
\]
and the magnetic susceptibility by the fluctuations of the magnetization
\[
\chi = \beta N \langle (m - \langle m \rangle)^2 \rangle = \beta N \langle (m^2) - \langle m \rangle^2 \rangle .
\]

In order to estimate the amount of data necessary for an accurate measurement of these quantities, we consider the fact that for \(n\) independent measurements the statistical error drops as \(1/\sqrt{n}\). The problem of determining how often we have independent measurements is very important and it will be discussed in detail later in this chapter.

### 13.3.1 The Program

In this section we discuss the program\(^{20}\) that implements the Monte Carlo simulation of the Ising model. The code in this section can be found in the accompanying software of this chapter in the directory Ising_Introduction.

In the design of the code, we follow the philosophy of modular programming. Different independent sections of the program will be coded in different files. This makes easier the development, maintenance and correction of the code by one or a team of programmers. A header file contains the definitions which are common for the code in one or more files. Then, all the parameters and common blocks are in one place and

\(^{20}\)The basic ideas in the program are taken from the book by Newmann and Barkema [4].
they are easier to modify for all program units in a unified way, therefore avoiding errors. In our case we have only one such file, named include.inc, whose code will be included in the beginning of each program unit using an include statement:

```fortran
!============ include.inc =============
implicit none
integer, parameter :: L = 12
integer, parameter :: N = L*L
integer, parameter :: XNN = 1, YNN = L
integer, dimension(N) :: s
real(8), dimension(0:4) :: prob
real(8) :: beta

common /lattice/ s
common /parameters/ beta, prob

!function definitions:
real(8) :: drandom
integer :: seed
common /randoms/ seed
```

The lattice size $L$ is a constant parameter, whereas the arrays and variables encoding the spins and the simulation parameters are put in common blocks. The array $s(N)$ stores the spin of each lattice site which take values $\pm 1$. The variable $beta$ is the temperature $\beta$ and the array $prob(0:4)$ stores the useful values of the acceptance ratios $A(\mu \rightarrow \nu)$ according to the discussion on page 508. The function $drandom()$ is the one discussed in section 11.1, which generates pseudorandom numbers uniformly distributed in the interval $(0,1)$ - 0 and 1 excluded. The parameters $XNN$ and $YNN$ are used for computing the nearest neighbors in the $X$ and $Y$ directions according to the discussion of section 13.3 on helical boundary conditions. For example, for an internal site $i$, $i+XNN$ is the nearest neighbor in the $+x$ direction and $i-YNN$ is the nearest neighbor in the $-y$ direction.

The main program is in the file main.f90 and drives the simulation:

```fortran
!============ main.f90 =============
program Ising2D
include 'include.inc'
integer :: start !start= 0 (cold)/1 (hot)
integer :: isweep, nsweep

nsweep = 1000
beta=0.21D0; seed=9873; start=1;
call init(start)
```
13.3. IMPLEMENTATION

In the beginning we set the simulation parameters. The initial configuration is determined by the value of start. If start=0, then it is a cold configuration and if start=1, then it is a hot configuration. The temperature is set by the value of beta and the number of sweeps of the lattice by the value of nsweep. One sweep of the lattice is defined by N attempted spin flips. The flow of the simulation is determined by the initial call to init, which performs all initialization tasks, and the subsequent calls to met and measure, which perform nsweep Metropolis sweeps and measurements respectively.

One level down lies the subroutine init. The value of start is passed through its argument so that the desired initial state is set:
At first the array prob(0:4) is initialized to the values of the acceptance ratios
\[ A(\mu \rightarrow \nu) = e^{-\beta(E_\nu-E_\mu)} = e^{-2\beta s^\mu_k \left( \sum_{(ik)} s^\mu_i \right)} \]. Those probabilities are going to be used when \( s_k \left( \sum_{(ik)} s^\mu_i \right) > 0 \) and the possible values are obtained when this expression takes the values 2 and 4. These are the values stored in the array prob(0:4), and we remember that the index of the array is the expression \( s_k \left( \sum_{(ik)} s^\mu_i \right) \), when it is positive.

The initial spin configuration is determined by the integer start. Using the select case block allows us to add more options in the future. When start=0 all spins are set equal to 1, whereas when start=1 each spin’s value is set to 1 with equal probability. The probability that \( \text{drandom}() < 0.5 \) is \( \frac{1}{2} \) in which case we set \( s(i)=1 \), otherwise (probability \( 1-\frac{1}{2} = \frac{1}{2} \)) we set \( s(i)=-1 \).

The heart of the program is the subroutine met() which attempts \( N \) Metropolis steps. It picks a random site \( N \) times and asks the question whether to perform a spin flip. This is done using the Metropolis algorithm by calculating the change in the energy of the system before and after the change of the spin value according to (13.23):

---

\[ \text{dE} = \frac{\text{change in energy}}{2}; \]

\[ \text{dE} = s_k \left( \sum_{(ik)} s^\mu_i \right) \]  

\[ \text{Remember that for the uniform distribution, } P(x < a) = a \]
13.3. **IMPLEMENTATION**

```plaintext
if (dE.le.0) then
  s(i) = -s(i) ! accept
else if (drandom() < prob(dE)) then
  s(i) = -s(i) ! accept
endif
enddo ! do k=1,N: end sweep
end subroutine met
```

The line

```plaintext
i = INT(N*drandom())+1
```

picks a site \( i=1, \ldots, N \) with equal probability. It is important that the value \( i=N+1 \) never appears, something that happens if \( \text{drandom}=1.0 \). This value has been excluded according to the discussion in section 11.1.

Next, we calculate the sum \( \left( \sum_{\langle ik \rangle} s_i^\mu \right) \) in (13.23). The nearest neighbors of the site \( i \) have to be determined and this happens in the lines

```plaintext
snn = 0
nn=1+XNN; if (nn.gt.N) nn=nn-N; snn = snn + s(nn)
nn=1-XNN; if (nn.lt.1) nn=nn+N; snn = snn + s(nn)
nn=1+YNN; if (nn.gt.N) nn=nn-N; snn = snn + s(nn)
nn=1-YNN; if (nn.lt.1) nn=nn+N; snn = snn + s(nn)
```

The variable \( \delta \) is set equal to the product \( s_k^\mu \left( \sum_{\langle ik \rangle} s_i^\mu \right) \). If it turns out to be negative, then the change in energy is negative and the spin flip is accepted. If it turns out to be positive, then we apply the criterion set by (13.22) by using the array \( \text{prob}(\delta) \), which has been set in the subroutine \( \text{init} \). The probability that \( \text{drandom} < \text{prob}(\delta) \) is equal to \( \text{prob}(\delta) \), in which case the spin flip is accepted. In all other cases, the spin flip is rejected and \( s(i) \) remains the same.

After each Metropolis sweep we perform a measurement. The code is minimal and simply prints the value of the energy and the magnetization to the stdout. The analysis is assumed to be performed by external programs. This way we keep the production code simple and store the raw data for a detailed and flexible analysis. The printed values of the energy and the magnetization will be used as monitors of the progress of the simulation, check thermalization and measure autocorrelation times. Plots of the measured values of an observable as a function of the Monte Carlo “time” are the so called “time histories”. Time histories of appropriately chosen observables should always be viewed and used in order to check the progress and spot possible problems in the simulation.
The subroutine `measure` calculates the total energy and magnetization (without the absolute value) by a call to the functions `E()` and `M()`, which apply the formulas (13.24) and (13.25).

```fortran
subroutine measure()
include 'include.inc'
integer :: E, M
print *, E(), M()
end subroutine measure
```

```fortran
integer function E()
include 'include.inc'
integer en, sum, i, nn
en = 0
do i = 1, N
  ! Sum of neighboring spins: only forward nn necessary in the sum
  sum = 0
  nn = i + XNN; if (nn.gt.N) nn = nn - N; sum = sum + s(nn)
  nn = i + YNN; if (nn.gt.N) nn = nn - N; sum = sum + s(nn)
  en = en + sum*s(i)
enddo
e = -en
end function E
```

```fortran
integer function M()
include 'include.inc'
M = SUM(s)
end function M
```

The compilation of the code is done with the command

```
> gfortran main.f90 met.f90 init.f90 measure.f90 drandom.f90 \\
    -o is
```

which results in the executable file `is`:

```
> ./is > out.dat
> less out.dat
-52 10
-48 40
-64 44
-92 64
......
```

The output of the program is two columns with the values of the to-
13.3. IMPLEMENTATION

tal energy and magnetization (without the absolute value). In order to construct their time histories we give the gnuplot commands:

```bash
plot "out.dat" using 1 with lines
plot "out.dat" using 2 with lines
plot "out.dat" using \((\text{($2>0)?$2:-$2})\) with lines
```

The last line calculates the absolute values of the second column. The C-like construct \((\text{($2>0)?$2:-$2})\) checks whether the expression \((\text{$2>0})\) is true. If it is, then it returns \text{$2}, otherwise it returns \text{-$2}.

13.3.2 Towards a Convenient User Interface

In this section we will improve the code, mostly at the user interface level. This is a nice exercise on the interaction of the programming language with the shell and the operating system. The code presented can be found in the accompanying software of this chapter in the directory Ising_Metropolis.

An annoying feature of the program discussed in the previous section is that the simulation parameters are hard coded and the user needs to recompile the program each time she changes them. This is not very convenient if she has to do a large number of simulations. Another notable change that needs to be made in the code is that the final configuration of the simulation must be saved in a file, in order to be read as an initial configuration by another simulation.

One of the parameters that the user might want to set interactively at run time is the size of the lattice \text{L}. But this parameter determines the required memory for the array \(s(N)\). Therefore we have to use dynamic memory allocation for this array using the intrinsic function \text{ALLOCATE}. Another problem is that the array \(s(N)\) needs to be accessible by several parts of the program and allocatable arrays cannot be put in a common block. Another mechanism for sharing data among different functions and subroutines is the use of \text{modules}. This is the preferable method of doing it in modern Fortran programs where the use of common blocks is discouraged. The shared data needs to be put between the following statements:

```fortran
module global_data
    implicit none
    SAVE
    ....
```
In place of the ... we can put variable declarations. We use the statement SAVE so that their values are saved between function and subroutine calls. The module has a name which in our case is global_data. Each program unit that needs to have access to its data needs to start with the statement use global_data:

```fortran
subroutine share_global_data
  use global_data
  implicit none
  ....
end subroutine share_global_data
```

In the file global_data.f90 we put all the global variables as follows:

```fortran
module global_data
  implicit none
  SAVE
  integer :: L
  integer :: N
  integer, allocatable :: xnn, ynn
  real(8), dimension(0:4) :: prob
  real(8) :: beta
  integer :: nsweep, start
  integer :: seed, ranlux_level
  real(8) :: acceptance
  character(1024) :: prog
end module global_data
```

The array `s(:)` is allocatable and its storage space will be allocated in the subroutine `init`. The variables `L`, `N`, `XNN` and `YNN` are not parameters anymore and their values will also be set in `init`. The new variables are `acceptance` which computes the fraction of accepted spin flips in a simulation, `ranlux_level` which determines the luxury level of RANLUX and `prog` which stores the command line name of the program that runs the simulation.

The main program has very few changes:

```fortran
!============= main.f90 ==============
program Ising2D
  use global_data
  implicit none
```
Notice the line `use global_data` which gives access to the data in the module `global_data`. This is the first line of all program units. The subroutine `endsim` finishes off the simulation. Its most important function is to store the final configuration to a file for later use.

The subroutine `init` is changed quite a bit since it performs most of the functions that have to do with the user interface:

```fortran
integer :: isweep

call init
do isweep = 1, nsweep
    call met
    call measure
end do
call endsim
end program Ising2D
```

!==================== init.f90 =====================
! start = 0: cold start
! start = 1: hot start
! start = 2: use old configuration
!====================
subroutine init
use global_data
implicit none
integer :: i, chk
real(8) :: obeta=1.0d0, r
integer :: OL=1
character(1024) :: buf
integer, parameter :: f_in=17 ! file unit
integer :: seeds(25)

!Define parameters from options:
L=-1;beta=-1.0D0;nsweep=-1;start=-1;seed=-1
ranlux_level=3
call get_the_options
if(start.EQ.0 .OR. start.EQ.1) then
    if(L < 0 ) call locerr("L has not been set."
    if(seed < 0 ) call locerr("seed has not been set."
    if(beta < 0.0D0) call locerr("beta has not been set."
endif !if(start.EQ.0 .OR. start.EQ.1)
! Derived parameters:
N=L*L;XNN=1;YNN=L
! Allocate memory for the spins:
ALLOCATE(s(N),STAT=chk)
if(chk > 0) call locerr("allocation failure for s(N)"
endif !if(start.EQ.0 .OR. start.EQ.1)
if(start < 0) call locerr("start has not been set."
```
if(nsweep < 0) call locerr('nsweep has not been set.')

! Initialize probabilities for E_\nu > E_mu
prob=0.0D0
do i=2,4,2 ! i = dE/2 = (E_\nu-E_mu)/2=2,4
  prob(i) = exp(-2.0D0*beta*i)
enddo
acceptance = 0.0D0

! Initial configuration: cold(0), hot(1), old(2)
select case(start)
!
! Case 0: Cold:
  call simmessage(6)
  call RLUXGO(ranlux_level,seed,0,0)
s = 1 ! All s(i) = 1
!
! Case 1: Hot:
  call simmessage(6)
  call RLUXGO(ranlux_level,seed,0,0)
do i=1,N
    call ranlux(r,1)
    if(r .lt. 0.5D0) then
      s(i) = 1
    else
      s(i) = -1
    endif
endo
!
! Case 2: Old:
  if(beta < 0.0D0) call locerr('beta has not been set.')
  open(f_in, file='conf', status='OLD', ERR=101)
  read(f_in,*),buf ! Read in a comment line
  read(f_in,'(A4,I5,A4,I5,A6,G28.17,A6,25116)')&
    buf,OL,buf,OL,buf,beta,buf,seeds
  if(L < 0) L = OL ! If L has not been set, read from file
  if(L /= 0L) & !/= the same as .NE. (not equal)
    call locerr('L different from the one read from conf.')
N=L*L; XNN=1; YNN=L
!
Allocate memory for the spins:
ALLOCATE(s(N),STAT=chk);
if(chk > 0) call locerr('allocation failure for s(N)')
call simmessage(6)
print '(A)', '# Reading configuration from file conf'
do i=1,N
  read(f_in,*,END=102) s(i)
  if(s(i) /= 1 .AND. s(i) /= -1)&
    call locerr('wrong value of spin')
13.3. IMPLEMENTATION

```fortran
enddo
close(f_in)
if(seed < 0) then !initialize from seeds read from file:
call RLUXIN(seeds)
else !option seed sets new seed:
call RLUXGO(ranlux_level,seed,0,0)
endif

! case default
print *,'init: start= ',start,' not valid. Exiting...'
stop 1
end select
!
return
!
here we put error messages:
101 call locerr('Configuration file conf not found.')
102 call locerr('File conf ended before reading all spins.')
end subroutine init
```

In the beginning, the simulation parameters that are to be determined by the user are given invalid default values. This way they are flagged as not been set. The subroutine `get_the_options` sets the parameters to the values that the user passes through the command line:

```
L=-1;beta=-1.0D0;nsweep=-1;start=-1;seed=-1
call get_the_options
```

Upon return of `get_the_options`, one has to check if all the parameters have been set to acceptable values. For example, if the user has forgotten to set the lattice size \( L \), the call to the subroutine `locerr` stops the program and prints the error message passed through its argument:

```
if(L < 0 )call locerr('L has not been set.')
```

When the value of \( N \) is calculated from \( L \), the program allocates memory for the array \( s(N) \):

```
N=L*L
ALLOCATE(s(N),STAT=chk)
if(chk > 0)call locerr('allocation failure for s(N)')
```

When memory allocation is successful, the variable `chk` is set to 0 by `ALLOCATE`. Otherwise we stop the program with a call to `locerr`.

\[^{21}\text{Found in the file options.f90.}\]
CHAPTER 13.  \( D = 2 \) ISING MODEL

Using the construct SELECT CASE(start) we set the initial configuration of the simulation. A value of start=0 sets all spins equal to 1. The subroutine simmmessage(f_unit) prints important information about the simulation to the unit f_unit. The random number generator RANLUX is initialized with a call to RLUXGO according to the discussion in section 11.2, page 461. The global variable ranlux_level is set to 3 by default, but the user can change it from the command line (see get_the_options). If start=0 the initial configuration is hot.

If start=2 we attempt to read a configuration stored in a file named conf. The format of the file is strictly set by the way we print the configuration in the subroutine endsim. If the file does not exist, the argument ERR=101 transfers the control of the program to the labeled statement with label 101. This is near the end of the program and stops the program with a call to locerr. In order to read the configuration properly we need to know the format of the data in the file conf which is, more or less, as follows:

```
# Configuration of 2d Ising model on square lattice....
Lx= 12  Ly= 12  beta= 0.21  seed= 3718479 5267541 12092770 ....
-1
 1
 1
 1
-1
.....
```

All comments of the first line are discarded in the character variable buf. The parameters L and beta of the stored configuration are stored in temporary variables OL, obeta, so that they can be compared with the values set by the user.

If the user provides a seed, then her seed will be used for seeding. Otherwise RANLUX is initialized to the state read from the file conf. Both choices are desirable in different cases: If the user wants to split a long simulation into several short runs, then each time she wants to restart the random number generator at exactly the same state. If she wants to use the same configuration in order to produce many independent results, then RANLUX has to produce different sequences of random numbers each time². This feature is coded in the lines:

\[ \text{Assuming that the configuration in conf is thermalized, the simulations become statistically independent after time } 2\tau, \text{ where } \tau \text{ is the autocorrelation time.} \]
13.3. IMPLEMENTATION

if (seed < 0) then ! initialize from seeds read from file:
call RLUXIN(seeds)
else ! option seed sets new seed:
call RLUXGO(ranlux_level, seed, 0, 0)
endif

When reading the spins, we have to make sure that they take only the legal values ±1 and that the data is enough to fill the array s(N)^2. Reading enough data is checked by the READ argument END=102. If the READ statement attempts to read past the end of the file conf, then the control of the program is transferred to the labeled statement with label 102. This will happen, e.g. if we attempt to read from a corrupted file.

The subroutine endsim saves the last configuration in the file conf and can be found in the file end.f90:

.equivalent comparison operators '>', '.GT.', '>=', '.GE.', '/=', '.NE.', '==', '.EQ.' etc.

```
subroutine endsim()
    use global_data
    implicit none
    integer, parameter :: f_out = 17
    integer :: i, seeds(25)

call RLUXUT(seeds)
call rename('conf', 'conf.old')
open(unit=f_out, file='conf')
write(f_out,'(A)')&
    '# Configuration of 2d Ising model on square lattice ...'
write(f_out,'(A4, I5, A4, I5, A6, G28.17, A6, 25I16)')&
    'Lx = ', L, ' Ly = ', L, ' beta = ', beta, ' seed = ', seed
do i=1,N
    write(f_out,'(I3)')s(i)
enddo
close(f_out)
print '(A,F7.3)', '# acceptance = ', &
    acceptance/DBLE(N)/DBLE(nsweep)
end subroutine endsim
```

The state of the random number generator RANLUX is saved by a call to RLUXUT which stores the necessary information in the array seeds. The call to the subroutine RENAME renames the file conf (if it exists) to the backup file conf.old. The format (A4, I5, A4, I5, A6, G28.17, A6, 25I16) has to be obeyed strictly during the output, as well as during the input of the configuration in the subroutine init.
The subroutine get_the_options() reads the parameters, passed through options from the command line. The choice to use options for passing parameters to the program has the advantage that they can be passed optionally and in any order desired. Let’s see how they work. Assume that the executable file is named is. The command

```
> ./is -L 10 -b 0.44 -s 1 -S 5342 -n 1000
```

will run the program after setting \( L = 10 \) (\(-L \ 10\)), \( \beta = 0.44 \) (\(-b \ 0.44\)), \( \text{start} = 1 \) (\(-s \ 1\)), \( \text{seed} = 5342 \) (\(-S \ 5342\)) and \( n\text{swEEP} = 1000 \) (\(-n \ 1000\)). The \(-L, -b, -s, -S, -n\) are options or switches and can be put in any order in the arguments of the command line. The arguments following an option are the values passed to the corresponding variables. Options can also be used without arguments, in which case a common use is to make the command function differently. In our case, the option \(-h\) is an option without an argument which makes the program to print a usage message and exit without running the simulation:

```
> ./is -h
Usage: ./is [options]
  -L: Lattice length \( (N=L*L) \)
  -b: beta
  -s: start \( (0 \) cold, \( 1 \) hot, \( 2 \) old config.)
  -S: seed
  -n: number of sweeps and measurements
  -u: seed from /dev/urandom
  -r: ranlux_level
Monte Carlo simulation of 2d Ising Model. Metropolis is used by default. Using the options, the parameters of the simulations must be set for a new run \( (\text{start}=0,1) \). If \( \text{start}=2 \), a configuration is read from the file conf.
```

This is a way to provide a short documentation on the usage of a program. Let’s see the code, which is found in the file options.f90:

```
!------------ options.f90 -------------
subroutine get_the_options
  use global_data
  use getopt_m  !from getopt.f90
  implicit none
  call getarg(0.prog)
```

\(^{25}\text{Remember how the option \(-l\) changes the results of the command \texttt{ls} if executed as \texttt{ls \ -l}.}\)
do
  select case( getopt( "-hL:b:s:S:n:r:u" ))
  case( 'L' )
    read(optarg.*)L
  case( 'b' )
    read(optarg.*)beta
  case( 's' )
    read(optarg.*)start
  case( 'S' )
    read(optarg.*)seed
  case( 'n' )
    read(optarg.*)nsweep
  case( 'r' )
    read(optarg.*)ranlux_level
  case( 'u' )
    open (28, file="/dev/urandom", &
    access="stream", form="unformatted")
    read (28) seed
    seed = ABS(seed)
    close(28)
  case( 'h' )
    call usage
  case( '?' )
    print *, 'unknown option', optarg
    stop
  case( char(0)) ! done with options
    exit
  case( '-' ) ! use -- to exit from options
    exit
  case default
    print *, 'unhandled option', optarg
  end select
end do
endo
d subroutine get_the_options

The command call getarg(0,prog) stores the name of the program in the command line to the character variable prog. The function getopt is a function written by Mark Gates and its code is in the file getopt.f90. It is programmed so that its usage is similar to the corresponding C function²⁶. The argument "-hL:b:s:S:n:r:u" in getopt defines the allowed options '-' , 'L', 'b', 's', 'S', 'n', 'r', 'u'. When a user passes one of those through the command line (e.g. -L 100, -h) the do loop takes us to the corresponding CASE. If an option does not take an argument (e.g. -h), then a set of commands can be executed, like call usage. If an

²⁶Read the comments in the file getopt.f90 for more information.
option takes an argument, this is marked by a semicolon in the argument of getopt (e.g. L:, b:, ...) and the argument can be accessed through the character variable optarg. For example, the statements

```plaintext
case ( 'L' )
  read(optarg,*)L
```

and the command line arguments -L 10 set optarg to be equal to '10'. Be careful, '10' is not a number, but a string of characters! In order to convert the character '10' to the integer 10 we use the command READ, where instead of a unit number in its arguments we put the variable name. We do the same for the other simulation parameters.

The subroutine locerr takes a character variable in its argument which prints it to the stderr together with the name of the program in the command line. Then it stops the execution of the program:

```plaintext
subroutine locerr(errmes)
  use global_data
  implicit none
  character(*) :: errmes
  write(0, '(A,A)', TRIM(prog), ':', TRIM(errmes), ' Exiting....')
  stop 1
end subroutine locerr
```

Note the use of the intrinsic function TRIM which removes the trailing blanks of a character variable. If we hadn’t been using it, the variable character(1024) :: prog would have been printed in 1024 character spaces, something that wouldn’t have been very pretty...

The subroutine usage is ... used very often! It is a constant reminder of the way that the program is used and helps users with weak long and/or short term memory!

```plaintext
subroutine usage

end subroutine usage

The subroutine simmessage is also quite important. It “labels” our results by printing all the information that defines the simulation. It is very important to label all of our data with this information, otherwise it can be dangerously useless! Imagine a set of energy measurements without knowing the lattice size and/or the temperature... Other useful information may turn out to be crucial, even though we might not appreciate it at programming time: The name of the computer, the operating system, the user name, the date etc. By varying the unit number in the argument, we can print the same information in any file we want.

subroutine simmessage(unit)
use global_data
implicit none
integer :: unit
character(100) :: user, host, mach, tdate
call GETLOG(user)
call GETENV('HOST', host)
call GETENV('HOSTTYPE', mach)
call FDATE (tdate)
write(unit, ' (A )')
' # #################################################################
write(unit, ' (A )')
' # 2d Ising Model, Metropolis algorithm on square lattice'
write(unit, ' ( 8A )')
' # Run on ', TRIM(host), ' (' ,TRIM(mach), ') by ', TRIM(user), '&
' on ',TRIM(tdate)
write(unit, ' ( A ,A )')
' # L = ',L , ' (N=L*L)' 
write(unit, ' ( A,A14 )')
' # seed = ',seed
write(unit, ' ( A,A112 ,A )')
' # nsweeps = ',nsweep , ' (No. sweeps)' 
write(unit, ' ( A,G28.17 )')
' # beta = ',beta 
write(unit, ' ( A,A14 ,A )')
' # start = ',start,&
' (0 cold, 1 hot, 2 old config)
end subroutine simmessage

The compilation can be done with the command:

> gfortran global_data.f90 getopt.f90 
  main.f90 init.f90 met.f90 measure.f90 end.f90 
  options.f90 ranlux.F -o is

It is important to note that the files containing modules, like global_data.f90 and getopt.f90, must precede the files with the code that use the mod-
ules.

In order to run the program we pass the parameters through options in the command line, like for example:

```
> /usr/bin/time ./is -L 10 -b 0.44 -s 1 -S 5342 -n 10000 \
  > & out.dat &
```

The command `time` is added in order to measure the computer resources (CPU time, memory, etc) that the program uses at run time.

A useful tool for complicated compilations is the utility `make`. Its documentation is several hundred pages which can be accessed through the `info` pages and the interested reader is encouraged to browse through it. If in the current directory there is a file named `Makefile` whose contents are

```make
# ####################################################################
# Makefile #################################################################
FC = gfortran
OBJ = global_data.o getopt.o ranlux.o \ 
    main.o init.o met.o measure.o end.o options.o
FFLAGS = -O2

is: $(OBJ)
  $(FC) $(FFLAGS) ^ -o @$

$(OBJ):  global_data.f90
options.o: getopt.f90
%.o: %.f90
  $(FC) $(FFLAGS) -c -o @$ $<
```

then this instructs the program `make` how to “make” the executable file `is`. What have we gained? In order to see that, run `make` for the first time. Then try making a trivial change in the file `main.f90` and rerun `make`. Then only the modified file is compiled and not the ones that have not been touched. This is accomplished by defining dependencies in `Makefile` which execute commands conditionally depending on the time stamps on the relevant files. Dependencies are defined in lines which are of the form keyword: word1 word2 .... For example, the line `options.o: getopt.f90` defines a dependency of the file `options.o` ²⁷²⁸

²⁷ Use the command `info make` or visit the www address `www.gnu.org/software/make/manual/make.html` ²⁸ Beware: one of the quirks of the program `make` is that all executable commands in `Makefile` must be in a line that starts exactly with a TAB. In the example `Makefile` shown above, the empty space before such lines is one TAB and not 8 empty spaces.
from the file getopt.f90. Lines 2-4 in the above Makefile define variables which can be used in the commands that follow. There are many predefined variables²⁹ in make which makes make programming easier. By using make in a large project, we can automatically link to libraries, pass complicated compiler options, do conditional compilation (depending, e.g., on the operating system, the compiler used etc), etc. A serious programmer needs to invest some time in order to use the full potential of make for the needs of her project³⁰.

13.4 Thermalization

The problem of thermalization can be important for some systems studied with Monte Carlo simulations. Even though it will not be so important in the simulations performed in this book, we will discuss it because of its importance in other problems. The reader should bear in mind that the thermalization problem becomes more serious with increasing system size and when autocorrelation times are large.

In a Monte Carlo simulation, the system is first put in a properly chosen initial configuration in order to start the Markov process. In section 12.2 we saw that when a system is in thermal equilibrium with a reservoir at a given temperature, then a typical state has energy that differs very little from its average value and belongs to a quite restricted region of phase space. Therefore, if we choose an initial state that is far from this region, then the system has to perform a random walk in the space of states until it finds the region of typical states. This is the thermalization process in a Monte Carlo simulation.

There are two problems that need to be addressed: The first one is the appropriate choice of the initial configuration and the second one is to find criteria that will determine when the system is thermalized. For the Ising model the initial configuration is either, (a) cold, (b) hot or (c) old state. It is obvious that choosing a hot state in order to simulate the system at a cool temperature is not the best choice, and the system will take longer to thermalize than if we choose a cold state or an old state at a nearby temperature. This is clearly seen in figure 13.7. Thermalization depends on the temperature and the system size, but it also depends on

²⁹Try the command make -p
³⁰At the time of the writing of this section, make had some problems with complicated Fortran compilations, which I hope they will be resolved in the future. You may also check out the program foray at code.google.com/p/foraytool or search the current "state of the art".
the physical quantity that we measure. Energy is thermalized faster than magnetization. In general, a local quantity thermalizes fast and a non local one slower. For the Ising model, thermalization is easier far from the critical temperature, provided that we choose an initial configuration in the same phase. It is easier to thermalize a small system rather than a large one.

The second problem is to determine when the system becomes thermalized and discard all measurements before that. One way is to start simulations using different initial states, or by keeping the same initial state and using a different sequence of random numbers. When the times histories of the monitored quantities converge, we are confident that the system has been thermalized. Figure 13.7 shows that the thermalization time can vary quite a lot.

A more systematic way is to compute an expectation value by removing an increasing number of initial measurements. When the results converge within the statistical error, then the physical quantity that we measure has thermalized. This process is shown in figures 13.10 and 13.11 where we progressively drop 0, 20, 50, 100, 200, 400, 800, 1600, 3200
and 6400 initial measurements until the expectation value of the magnetization stabilizes within the limits of its statistical error.

### 13.5 Autocorrelations

In order to construct a set of independent measurements using a Markov process, the states put in the sample should be statistically uncorrelated. But for a process using the Metropolis algorithm this is not possible. The next state differs from the previous one by at most one value of their spins. We would expect that we could obtain an almost statistically independent configuration after one spin update per site, a so called sweep of the lattice. This is indeed the case for the Ising model for temperatures far from the critical region. But as one approaches $\beta_c$, correlations between configurations obtained after a few sweeps remain strong. It is easy to understand why this is happening. As the correlation length $\xi$ \[12.46\] becomes much larger than a few lattice spacings, large clusters of same spins are formed, as can be seen in figure \[13.32\]. For two statistically independent configurations, the size, shape and position of those clusters should be quite different. For a single flip algorithm, like the Metropolis
algorithm, this process takes a lot of time.

For the quantitative study of autocorrelations between configurations we use the autocorrelation function. Consider a physical quantity $O$ (e.g. energy, magnetization, etc) and let $O(t)$ be its value after Monte Carlo “time” $t$. $t$ can be measured in sweeps or multiples of it. The autocorrelation function $\rho_O(t)$ of $O$ is

$$\rho_O(t) = \frac{\langle (O(t') - \langle O \rangle)(O(t' + t) - \langle O \rangle) \rangle}{\langle (O - \langle O \rangle)^2 \rangle},$$

(13.31)

where $\langle \ldots \rangle_\nu$ is the average value over the configurations in the sample for $t' < t_{\text{max}} - t$. The normalization is such that $\rho_O(0) = 1$.

The above definition reminds us the correlation function of spins in space (see equation (12.45)) and the discussion about its properties is similar to the one of section 12.4. In a few words, when the value of $O$ after time $t$ is strongly correlated to the one at $t = 0$, then the product in the numerator in (13.31) will be positive most of the time and the value

---

30The Metropolis algorithm changes the clusters mostly by modifying their boundaries, since it is less probable to change the value of a spin in the cluster where all its nearest neighbors have the same spin.
of $\rho_\mathcal{O}(t)$ will be positive. When the correlation is weak, the product will be positive and negative the same number of times and $\rho_\mathcal{O}(t)$ will be almost zero. In the case of anti-correlations $\rho_\mathcal{O}(t)$ is negative. Negative values of $\rho_\mathcal{O}(t)$ occur, but these are artifacts of the finite size of the sample and should be rejected.

Asymptotically $\rho_\mathcal{O}(t)$ drops exponentially

$$\rho_\mathcal{O}(t) \sim e^{-t/\tau_\mathcal{O}}.$$  \hfill (13.32)

$\tau_\mathcal{O}$ is the time scale of decorrelation of the measurements of $\mathcal{O}$ and it is called the autocorrelation time of $\mathcal{O}$. After time $2\tau_\mathcal{O}$, $\rho_\mathcal{O}(t)$ has dropped to the $1/e^2 \approx 14\%$ of its initial value and then we say that we have an independent measurement of $\mathcal{O}$. Therefore, if we have $t_{\text{max}}$ measurements, the number of independent measurements of $\mathcal{O}$ is

$$n_\mathcal{O} = \frac{t_{\text{max}}}{2\tau_\mathcal{O}}.$$  \hfill (13.33)

For expensive measurements we should measure every $\sim \tau_\mathcal{O}$ sweeps. If the cost of measurement is not significant, then we usually measure

---

Figure 13.10: Magnetization per site for the Ising model with $L = 100$ and $\beta = 0.48$. Thermalization starts from a hot state.
Figure 13.11: Magnetization per site for the Ising model with $L = 100$ and $\beta = 0.48$. We calculate the expectation value $\langle m \rangle$ by neglecting an increasing number of “thermalization sweeps” from the measurements in figure 13.10. When the neglected sweeps reach the thermalized state, the result converges to $\langle m \rangle = 0.880(1)$. This is an indication that the system has thermalized.

more often, since there is still statistical information even in slightly correlated configurations. An accurate determination of $\tau_O$ is not easy since it requires measuring for $t \gg \tau_O$.

An example is shown in figure 13.12 for the case of the magnetization ($O = m$). We calculate the function $\rho_m(t)$ and we see that a fit to equation (13.32) is quite good for $\tau_m = 235 \pm 3$ sweeps. The calculation is performed on a sample of $10^6$ measurements with 1 measurement/sweep. Therefore the number of independent measurements is $\approx 10^6/(2 \times 235) \approx 2128$.

Another estimator of the autocorrelation time is the so called integrated autocorrelation time $\tau_{\text{int},O}$. Its definition stems from equation (13.32) where we take

$$\tau_{\text{int},O} = \int_0^{+\infty} dt \rho_O(t) \sim \int_0^{+\infty} dt e^{-t/\tau_O} = \tau_O.$$ (13.34)

The values of $\tau_{\text{int},O}$ and $\tau_O$ differ slightly due to systematic errors that
13.5. AUTOCORRELATIONS

Figure 13.12: The autocorrelation function of the magnetization $\rho_m(t)$ for the Ising model for $L = 100$, $\beta = 0.42$. We see its exponential decay and that $\tau_m \approx 200$ sweeps. One can see the finite sample effects (the sample consists of about 1,000,000 measurements) when $\rho$ starts fluctuating around 0.

come from the corrections\footnote{In our calculations, we will see differences of the order of 10%. The actual values can be different but their scaling properties are same.} to equation (13.32). The upper limit of the integral is cut off by a maximum value $t_{\text{max}}$

$$
\tau_{\text{int},\mathcal{O}}(t_{\text{max}}) = \int_0^{t_{\text{max}}} dt \rho_{\mathcal{O}}(t).
$$

(13.35)

For large enough $t_{\text{max}}$ we observe a plateau in the plot of the value of $\tau_{\text{int},\mathcal{O}}(t_{\text{max}})$ which indicates convergence, and we take this as the estimator of $\tau_{\text{int},\mathcal{O}}$. For even larger $t_{\text{max}}$, finite sample effects enter in the sum that should be discarded.

This calculation is shown in figure 13.14 where we used the same measurements as the ones in figure 13.12. We find that $\tau_{\text{int},m} = 217(3)$ sweeps, which is somewhat smaller than the autocorrelation time that we calculated using the exponential fit to the autocorrelation function. If we are interested in the scaling properties of the autocorrelation time with the size of the system $L$ or the temperature $\beta$, then this difference is
Figure 13.13: The autocorrelation function shown in figure 13.12 of the magnetization $\rho_m(t)$ for the Ising model for $L = 100$, $\beta = 0.42$ in a log plot. The plot shows a fit to $Ce^{-t/\tau}$ (see equation (13.32)) with $\tau = 235(3)$ sweeps.

not important\footnote{The actual value of $\tau_\infty$ is used in computing the number of independent configurations from (13.33) and the correction of the statistical error in (13.47). In both cases, the difference in the values of $\tau_\infty$ is not significant. For (13.47), this is because the concept of the error of the error is slightly fuzzy.}. The calculation of $\tau_{int,0}$ is quicker since it involves no fitting\footnote{As we will see later, there are other, smaller autocorrelation times present as well. These are not taken into account in the definition of the integrated autocorrelation time and the detailed study of the autocorrelation function is necessary if more accuracy is desired.}.

Autocorrelation times are not a serious problem away from the critical region. Figures 13.15 and 13.16 show that they are no longer than a few sweeps and that they are independent of the system size $L$. As we approach the critical region, autocorrelation times increase. At the critical region we observe scaling of their values with the system size, which means that for large $L$ we have that

$$\tau \sim L^{z}.$$  \hspace{1cm} (13.36)

This is the phenomenon of critical slowing down. For the Metropolis
13.6. **STATISTICAL ERRORS**

![Graph](image)

**Figure 13.14:** Calculation of the integrated autocorrelation time of the magnetization for the same data used in figure 13.19. There is a plateau in the values of \( \tau_{\text{int}, m} \) for \( \tau_1 = 214(1) \) sweeps and a maximum for \( \tau_2 \approx 219.5 \) sweeps. The fall from \( \tau_2 \) to \( \approx \tau_1 \) is due to the negative values of \( m(t) \) due to the noise coming from finite sample effects. We estimate that \( \tau_{\text{int}, m} = 217(3) \) sweeps.

Algorithm and the autocorrelation time of the magnetization, we have that \( z = 2.1665 \pm 0.0012 \) [60]. This is a large value and that makes the algorithm expensive for the study of the critical properties of the Ising model. It means that the simulation time necessary for obtaining a given number of independent configurations increases as

\[
t_{\text{CPU}} \sim L^{d+z} \approx L^{4.17}.
\]  

(13.37)

In the next chapter, we will discuss the scaling relation (13.36) in more detail and present new algorithms that reduce critical slowing down drastically.

### 13.6 Statistical Errors

The estimate of the expectation value of an observable from its average value in a sample gives no information about the quality of the measurement. The complete information is provided by the full distribution, but
in practice we are usually content with the determination of the “statistical error” of the measurement. This is defined using the assumption that the distribution of the measurements is Gaussian, which is a very good approximation if the measurements are independent. The statistical error is determined by the fluctuations of the values of the observable in the sample around its average (see discussion in section 12.2 and in particular equation (12.27)). Statistical errors can be made to vanish, because they decrease as the inverse square root of the size of the sample.

Besides statistical errors, one has systematic errors, which are harder to control. Some of them are easier to control (like e.g. poor thermalization) and others maybe hard even to realize their effect (like e.g. a subtle problem in a random number generator). In the case of a discrete, finite, lattice, approximating a continuous theory, there are systematic errors due to the discretization and the finite size of the system. These errors are reduced by simulating larger systems and by using several techniques (e.g. finite size scaling) in order to extrapolate the results to the thermodynamic limit. These will be studied in detail in the following chapter.
13.6. STATISTICAL ERRORS

Figure 13.16: The autocorrelation time of the magnetization for the Ising model at (low) temperature $\beta = 0.65$ for $L = 5, 10, 20, 40$. The autocorrelation time in sweeps is independent of $L$.

### 13.6.1 Errors of Independent Measurements

Using the assumption that the source of statistical errors are the thermal fluctuations around the average value of an observable, we conclude that its expectation value can be estimated by the mean of the sample and its error by the error of the mean. Therefore if we have a sample of $n$ measurements $O_0, O_1, \ldots, O_{n-1}$, their mean is an estimator of $\langle O \rangle$

$$\langle O \rangle = \frac{1}{n} \sum_{i=0}^{n-1} O_i.$$ (13.38)

The error of the mean is an estimator of the statistical error $\delta O$

$$(\delta O)^2 \equiv \sigma_O^2 = \frac{1}{n-1} \left\{ \frac{1}{n} \sum_{i=0}^{n-1} (O_i - \langle O \rangle)^2 \right\} = \frac{1}{n-1} \left( \langle O^2 \rangle - \langle O \rangle^2 \right).$$ (13.39)

The above equations assume that the sample is a set of statistically independent measurements. This is not true in a Monte Carlo simulation due to the presence of autocorrelations. If the autocorrelation time, measured
Figure 13.17: The autocorrelation function of the magnetization for the Ising model for $L = 40$. It shows how the autocorrelation time increases as we approach the critical temperature from the disordered (hot) phase.

in number of measurements, is $\tau_\mathcal{O}$, then according to equation \ref{eq:13.33} we will have $n_\mathcal{O} = n/(2\tau_\mathcal{O})$ independent measurements. One can show that in this case, the statistical error in the measurement of $\mathcal{O}$ is

$$
(\delta \mathcal{O})^2 = \frac{1 + 2\tau_\mathcal{O}}{n-1} (\langle \mathcal{O}^2 \rangle - \langle \mathcal{O} \rangle^2)
$$

(13.40)

If $\tau_\mathcal{O} \ll 1$, then we obtain equation \ref{eq:13.39}. If $\tau_\mathcal{O} \gg 1$

$$
(\delta \mathcal{O})^2 \approx \frac{2\tau_\mathcal{O}}{n-1} (\langle \mathcal{O}^2 \rangle - \langle \mathcal{O} \rangle^2)
\approx \frac{1}{(n/2\tau_\mathcal{O})} (\langle \mathcal{O}^2 \rangle - \langle \mathcal{O} \rangle^2)
\approx \frac{1}{n_\mathcal{O} - 1} (\langle \mathcal{O}^2 \rangle - \langle \mathcal{O} \rangle^2)
$$

(13.41)

which is nothing but equation \ref{eq:13.39} for $n_\mathcal{O}$ independent measurements (we assumed that $1 \ll n_\mathcal{O} \ll n$). The above relation is consistent with our assumption that measurements become independent after time $\sim 2\tau_\mathcal{O}$.

\footnote{See also chapter 4.1 in \cite{61}}
### 13.6. STATISTICAL ERRORS

Figure 13.18: The autocorrelation function of the magnetization for the Ising model for $L = 40$. It shows how the autocorrelation time increases as we approach the critical temperature from the ordered (cold) phase.

In some cases, the straightforward application of equations (13.41) is not convenient. This happens when, measuring the autocorrelation time according to the discussion in section 13.5, becomes laborious and time consuming. Moreover, one has to compute the errors of observables that are functions of correlated quantities, like in the case of the magnetic susceptibility (13.30). The calculation requires the knowledge of quantities that are not defined on one spin configuration, like $\langle m \rangle$ and $\langle m^2 \rangle$ (or $(m_i - \langle m \rangle)$ on each configuration $i$). After these are calculated on the sample, the error $\delta \chi$ is not a simple function of $\delta \langle m \rangle$ and $\delta \langle m^2 \rangle$. This is because of the correlation between the two quantities and the well known formula of error propagation $\left( \delta (\langle m^2 \rangle - \langle m \rangle^2) \right)^2 = \left( \delta \langle m^2 \rangle \right)^2 + \left( \delta \langle m \rangle \right)^2$ cannot be applied.

#### 13.6.2 Jackknife

The simplest solution to the problems arising in the calculation of statistical errors discussed in the previous section is to divide a sample into blocks or bins. If one has $n$ measurements, she can put them in $n_b$ “bins”
and each bin is to be taken as an independent measurement. This will be true if the number of measurements per bin $b = (n/n_b) \gg \tau_O$. If $O_i^b$ $i = 0, \ldots, n_b - 1$ is average value of $O$ in the bin $i$, then the error is given by (13.39)

$$
(\delta O)^2 = \frac{1}{n_b - 1} \left\{ \frac{1}{n_b} \sum_{i=0}^{n_b-1} (O_i^b - \langle O^b \rangle)^2 \right\}
$$

This is the binning or blocking method and it is quite simple in its use. Note that quantities, like the magnetic susceptibilities, are calculated in each bin as if the bin were an independent sample. Then the error is easily calculated by equation (13.42). If the bin is too small and the samples are not independent, then the error is underestimated by a factor of $2\tau_O/(n_b - 1)$ (see equation (13.40)). The bins are statistically independent if $b \sim 2\tau_O$. If $\tau_O$ is not a priori known we compute the error (13.42) by decreasing the number of bins $n_b$. When the error is not increasing anymore and takes on a constant value, then the calculation converges to the true statistical error.

But the method of choice in this book is the jackknife method. It is more stable and more reliable, especially if the sample is small. The

Figure 13.19: The autocorrelation function for the Ising model for $\beta = 0.4407 \approx \beta_c$ and different $L$. We observe the increase of the autocorrelation time with the system size in the critical region.
The integrated autocorrelation time $\tau_{\text{int,m}}$ for $\beta = \beta_c$ in a logarithmic scale. The continuous line is the fit to $0.136(10)L^{2.067(21)}$. The expected result from the bibliography is $z = 2.1665(12)$ and the difference is a finite size effect.

The basic idea is similar to the binning method. The difference is that the bins are constructed in a different way and equation (13.42) is slightly modified. The data is split in $n_b$ bins which contain $b = n - (n/n_b)$ elements as follows: The bin $j$ contains the part of the sample obtained after we erase the contents of the $j$-th bin of the binning method from the full sample $O_0, \ldots, O_{n-1}$. The procedure is depicted in figure 13.21. We calculate the average value of $O$ in each bin and we obtain $O^b_0, O^b_1, \ldots, O^b_{n_b-1}$. Then the statistical error in the measurement of $O$ is

$$
(\delta O)^2 = \sum_{j=0}^{n_b-1} (O^b_j - \langle O^b \rangle)^2 = n_b \left( \langle (O^b)^2 \rangle - \langle O^b \rangle^2 \right).
$$

In order to determine the error, one has to vary the number of bins and check for the convergence of (13.43), like in the case of the binning method.

For more details and proofs of the above statements, the reader is referred to the book of Berg [5]. Appendix 13.8.1 provides examples and a program for the calculation of jackknife errors.
Figure 13.21: The jackknife method applied on a sample of \( n = 20 \) measurements. The data is split to \( n_b = 5 \) bins and each bin contains \( b = n - (n/n_b) = 20 - 4 = 16 \) measurements (the black disks). We calculate the average value \( \langle O \rangle_i \) in each bin and, by using them, we calculate the error \( \delta O = \sqrt{n_b \langle [\langle O \rangle_i^2 \rangle - \langle O \rangle_i^2] \rangle} \).

### 13.6.3 Bootstrap

Another useful method for the estimation of statistical errors is the bootstrap method. Suppose that we have \( n \) independent measurements. From these we create \( n_S \) random samples as follows: We choose one of the \( n \) measurements with equal probability. We repeat \( n \) times using the same set of \( n \) measurements - i.e. by putting the chosen measurements back to the sample. This means that on the average \( \sim 1 - 1/e \approx 63\% \) of the sample will consist of the same measurements. In each sample \( i = 0, \ldots, n_S - 1 \) we calculate the average values \( \langle O \rangle_i \) and from those

\[
\langle O^S \rangle = \frac{1}{n_S} \sum_{i=0}^{n_S-1} O_i^S,
\]

and

\[
\langle (O^S)^2 \rangle = \frac{1}{n_S} \sum_{i=0}^{n_S-1} (O_i^S)^2.
\]

The estimate for the error in \( \langle O \rangle \) is\footnote{Notice that the right hand side of equation (13.46) is not divided by \( 1/(n_s - 1) \).}

\[
(\delta O)^2 = \langle (O^S)^2 \rangle - \langle O^S \rangle^2.
\]

We stress that the above formula gives the error for independent measurements. If we have non negligible autocorrelation times, then we must use the correction

\[
(\delta O)^2 = (1 + 2\tau_O) \left( \langle (O^S)^2 \rangle - \langle O^S \rangle^2 \right)
\]

\[\text{(13.47)}\]
Appendix 13.8.2 discusses how to use the bootstrap method in order to calculate the true error $\delta O$ without an a priori knowledge of $\tau_0$. For more details, the reader is referred to the articles of Bradley Efron [62]. In appendix 13.8.2 you will find examples and a program that implements the bootstrap method.

### 13.7 Appendix: Autocorrelation Function

This appendix discusses the technical details of the calculation of the autocorrelation function (13.31) and the autocorrelation time given by equations (13.32) and (13.34). The programs can be found in the directory Tools in the accompanying software.

If we have a finite sample of $n$ measurements $O(0), O(1), \ldots, O(n-1)$, then we can use the following estimator for the autocorrelation function, given by equation (13.31),

$$
\rho_O(t) = \frac{1}{n-t-1} \sum_{t'=0}^{n-1-t} \left( O(t') - \langle O \rangle_0 \right) \left( O(t'+t) - \langle O \rangle_t \right),
$$

(13.48)

where the average values are computed from the equations:

$$
\langle O \rangle_0 \equiv \frac{1}{n-t} \sum_{t'=0}^{n-1-t} O(t'), \quad \langle O \rangle_t \equiv \frac{1}{n-t} \sum_{t'=0}^{n-1-t} O(t'+t).
$$

(13.49)

The constant $\rho_0$ is chosen so that $\rho_O(0) = 1$.

The program for the calculation of (13.48) and the autocorrelation time (13.34) is listed below. It is in the file autoc.f90 and you should read the comments embedded in the code for explanations of the most important steps.

```fortran
! file : autoc.f90
MODULE rho_function
   implicit none
SAVE
integer :: NMAX, tmax
```

---

38 Alternatively one can take $\langle O \rangle_0 = \langle O \rangle_t = (1/n) \sum_{t'=0}^{n-1} O(t')$ without noticeable difference for $t \ll n$. The choice in (13.48) results in a more accurate calculation and smaller finite sample effects. The choice (13.48), instead of $\rho_O(t) \propto (1/(n-t)) \sum_{t'=0}^{n-1-t} O(t')O(t'+t) - \langle O \rangle_0 \langle O \rangle_t$, has smaller roundoff errors.

!=====================================================================

The calculation of the autocorrelation function is put in a separate mod-
ule rho_function which can be used by any of your programs. After
the statement CONTAINS we can add code for functions and subroutines
which can be accessed by any program unit that uses the module. The
module makes global variables, like NMAX, tmax and prog, accessible to
all program units that use the module.

The compilation is done with the commands

> gfortran -O2 getopt.f90 autoc.f90 -o autoc

If our data is written in a file named data in one column, then the
calculation of the autocorrelation function and the autocorrelation time
is done with the command

> cat data | ./autoc > data.rho

The results are written to the file data.rho in three columns. The first one
is the time t, the second one is $\rho(t)$ and the third one is $\tau_{\text{int,$\rho$}}(t)$ (equa-
tion (13.35)). The corresponding plots are constructed by the gnuplot
commands:

gnuplot> plot "data.rho" using 1:2 with lines

---

The explicit interface of the function or the subroutine is known to all program
units that use the module.
If we wish to increase the maximum number of data \( N_{\text{MAX}} \) or the maximum time \( t_{\text{max}} \), then we use the options \(-n\) and \(-t\) respectively:

```
> cat data | autoc -n 20000000 -t 20000 > data.rho
```

For doing all the work at once using gnuplot, we can give the command:

```
gnuplot> plot "<./is -L 20 -b 0.4407 -s 1 -S 345 -n 4000001
  grep -v '#' | awk '{print ($2>0)?$2:-$2;}' \| autoc -t 500" using 1:2 with lines
```

The above command is long and it is broken into 3 lines for better printing. You can type it in one line by removing the trailing \.

A script that works out many calculations together is listed below. It is in the file `autoc_L` and computes the data shown in figure 13.19.

```bash
#!/bin/tcsh -f
set nmeas  = 2100000
set Ls    = (5 10 20 40 60 80)
set beta  = 0.4407
set tmax  = 2000
foreach L ($Ls)
  set N   = 'awk -v L=$L "BEGIN{print L*L}"'
  set rand = 'perl -e "srand(); print int(3000000*rand())+1;"'
  set out  = outL$Lb$beta
  echo "Running L$L b$beta"
  ./is -L $L -b $beta -s 1 -S $rand -n $nmeas > $out
  echo "Autocorrelations L$L b$beta"
  grep -v '#' $out | \
  awk -v N=$N 'NR>100000{print ($2>0)?($2/N):(-$2/N)}'
  autoc -t $tmax > $out.rhom
end
```

Then we give the gnuplot commands:

```
gnuplot> plot "outL5b0.4407.rhom" u 1:2 w lines title "5"
gnuplot> replot "outL10b0.4407.rhom" u 1:2 w lines title "10"
gnuplot> replot "outL20b0.4407.rhom" u 1:2 w lines title "20"
gnuplot> replot "outL40b0.4407.rhom" u 1:2 w lines title "40"
gnuplot> replot "outL60b0.4407.rhom" u 1:2 w lines title "60"
gnuplot> replot "outL80b0.4407.rhom" u 1:2 w lines title "80"
```
The plots in figure 13.17 are constructed in a similar way.
For the calculation of \( \tau_m \) we do the following:

```bash
gnuplot> f(x) = c * exp(-x/t)
 gnuplot> set log y
 gnuplot> plot [:1000] "outL40b0.4407.rhom" u 1:2 with lines
 gnuplot> c = 1 ; t = 300
 gnuplot> fit [150:650] f(x) "outL40b0.4407.rhom" u 1:2 via c,t
 gnuplot> plot [:1000] "outL40b0.4407.rhom" u 1:2 w lines,f(x)
 gnuplot> plot [:] "outL40b0.4407.rhom" u 1:3 w lines
```

where in the last line we compute \( \tau_{int,m} \). The fit command is just an example and one should try different fitting ranges. The first plot command shows graphically the approximate range of the exponential falloff of the autocorrelation function. We should vary the upper and lower limits of the fitting range until the value of \( \tau_m \) stabilizes and the \( \chi^2/dof \) is minimized\(^{40}\). The \( \chi^2/dof \) of the fit can be read off from the output of the command `fit`.

```
.....
degrees of freedom (FIT_NDF) : 449
rms of residuals (FIT_STDFIT) = sqrt(WSSR/ndf) : +/- 0.000939201
variance of residuals(reduced chisquare) = WSSR/ndf: 8.82099e-07
```

Final set of parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
<th>Asymptotic Standard Error</th>
</tr>
</thead>
<tbody>
<tr>
<td>c</td>
<td>0.925371</td>
<td>+/- 0.0003773 (0.04078%)</td>
</tr>
<tr>
<td>t</td>
<td>285.736</td>
<td>+/- 0.1141 (0.03995%)</td>
</tr>
</tbody>
</table>

from the line “variance of residuals”. From the next lines we read the values of the fitted parameters with their errors\(^{41}\) and we conclude

\(^{40}\)For the data \( \{ (x_i, y_i) \} \), \( i = 1, \ldots, n \) with error \( \delta y_i \) which are fitted to \( f(x; c, t) = ce^{-x/t} \), the \( \chi^2(c, t) = \sum_{i=1}^{n}(y_i - f(x_i; c, t))^2/\delta y_i^2 \). The \( \chi^2/dof \) is normalized to the number of degrees of freedom (dof = degrees of freedom = \( n - 2 \)) which is the number of data points \( n \) used in the fit minus the number of fitting parameters (here \( c, t \) which makes 2 parameters).

\(^{41}\)The acceptable \( \chi^2/dof \sim 1 \). Since we don’t calculate the errors of the autocorrelation functions, the \( \chi^2/dof \) is not properly normalized. The program sets \( \delta y_i = 1 \) \( \forall i \).

\(^{42}\)In the parentheses we see the confidence level. This is defined as the probability that the parameters are within the range defined by the error. For a correct calculation of the confidence level, every point should be weighted by its error - in our example
that $\tau_m = 285.7 \pm 0.1$. We stress that this is the statistical error of the fit for the given fitting range. But usually the largest contributions to the error come from systematic errors, which, in our case, are seen by varying the fitting range\footnote{For a careful calculation, one should also try more functions that include corrections to the asymptotic behavior.}. By trying different fitting ranges and using the criterion that the minimum $\chi^2$/dof doubles its minimum value, we find that $\tau_m = 285(2)$.

In our case the largest systematic error comes from neglecting the effect of smaller autocorrelation times. These make non negligible contributions for small $t$.

By fitting to

$$f(t) = c e^{-t/\tau},$$

we have taken into account only the largest autocorrelation time.

One should take into account also the smaller autocorrelation times. In this case we expect that $\rho_m(t) \sim a_1 e^{-t/\tau_1} + a_2 e^{-t/\tau_2} + \ldots$. We find that the data for the autocorrelation function fit perfectly to the function

$$h(x) = a_1 e^{-x/\tau_1} + a_2 e^{-x/\tau_2} + a_3 e^{-x/\tau_3}.$$  

(13.51)

As we can see in figures \[13.22\] and \[13.23\] the small $t$ fit is excellent and the result for the dominant autocorrelation time is $\tau_m \equiv \tau_1 = 286.3(3)$. The secondary autocorrelation times are $\tau_2 = 57(3), \tau_3 = 10.5(8)$ which are considerably smaller than $\tau_1$.

The commands for the analysis are listed below:

```bash
gnuplot> h(x) = a1*exp(-x/t1) + a2*exp(-x/t2) + a3*exp(-x/t3)

gnuplot> a1 = 1;  t1 = 285; a2 = 0.04; t2 = 56; \a3 = 0.03; t3 = 10

gnuplot> fit [1:600] h(x) "out40b.4407.rhom" \using 1:2 via a1,t1,a2,t2,a3,t3

... Final set of parameters Asymptotic Standard Error

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
<th>+/-</th>
<th>Error</th>
</tr>
</thead>
<tbody>
<tr>
<td>a1</td>
<td>0.922111</td>
<td>+/- 0.001046</td>
<td>0.1135%</td>
</tr>
<tr>
<td>t1</td>
<td>286.325</td>
<td>+/- 0.2354</td>
<td>0.08221%</td>

<td>0.0300761</td>
<td>+/- 0.001558</td>
<td>5.18%</td>
</tr>
</tbody>
</table>

this is not happening and this is the reason why the confidence level is so low. A value below 5% is too low and it indicates that the model needs corrections. It is also assumed that the distribution of the measurements is Gaussian and if not, the computed numerical values are only indicative.
Figure 13.22: Fit of the autocorrelation function $\rho_m(t)$ to the functions $f(t) = c e^{-t/\tau}$ and $h(t) = a_1 e^{-t/\tau_1} + a_2 e^{-t/\tau_2} + a_3 e^{-t/\tau_3}$. For large times $f(t) \approx h(t)$, but $h(t)$ is necessary in order to capture the small $t$ behavior. This choice results in $\tau_m = \tau = \tau_1$. The values of the parameters are given in the text. The vertical axes are in logarithmic scale.

$$t_3 = 10.5227 \pm 0.8382 (7.965\%)$$

```
gnuplot> plot [:150][0.5:] "outL40b0.4407.rhom" using 1:2 \ with lines notit.h(x) ,f(x)

```

13.8 Appendix: Error Analysis

13.8.1 The Jackknife Method

In this section we present a program that calculates the errors using the jackknife method discussed in section 13.6.2. Figure 13.21 shows the division of the data into bins. For each bin we calculate the average value of the quantity $O$ and then we use equation (13.43) in order to calculate the error. The program is in the file jack.f90 which you can find in the directory Tools in the accompanying software. The program
Figure 13.23: The plot of figure [13.22] for small times where the effect of smaller autocorrelation times is most clearly seen.

calculates \( \langle O \rangle, \delta O, \chi \equiv \langle (O - \langle O \rangle)^2 \rangle \) and \( \delta \chi \).

print '(A)', ' -d : Max. no. of data points read'
print '(A)', ' Computes <o>, chi= (<o^2>_<o>^2)'
print '(A)', ' Data is in one column from stdin.'
For the compilation we use the command

```
> gfortran -O2 getopt.f90 jack.f90 -o jack
```

If we assume that our data is in one column in the file data, the command that calculates the jackknife errors using 50 bins is:

```
> cat data | jack -j 50
```

The program has set a maximum of \( \text{MAXDAT}=1,000,000 \) measurements. If we need to analyze more data, we have to use the switch \(-d\). For example, for 2,000,000 measurements, use \(-d\) 2000000. The program reads data from the stdin and we can construct filters in order to do complicated analysis tasks. For example, the analysis of the magnetization produced by the output of the Ising model program can be done with the command:

```
> ./is -L 20 -b 0.4407 -s 1 -S 342 -n 2000000 | grep -v # | \nawk -v L=20 '{ print ($2>0)?($2/(L*L)):(-$2/(L*L))}' | \n./jack -j 50 -d 2000000 | grep -v # | \nawk -v b=0.4407 -v L=20 '{ print $1,$2,b*L*L,$3,b*L*L*$4}'
```

The command shown above can be written in one line by removing the backslashes (\'\') at the end of each line. Let’s explain it in detail: The first line runs the program is for the Ising model with \( N = L \times L = 20 \times 20 \) lattice sites \((-L 20)\) and \( \beta = 0.4407 \) \((-b 0.4407)\). It starts the simulation from a hot configuration \((-s 1)\) and makes \( 2,000,000 \) measurements \((-n 2000000)\). The command grep \(-v\) filters out the comments from the output of the program, which are lines starting with a \#. The second line calls awk and defines the awk variable L to be equal to 20 \((-v L=20)\). For each line in its input, it prints the absolute value of the second column \((\$2)\) divided by the number of lattice sites \(L \times L\). The third line makes the jackknife calculation of the average values of \( \langle m \rangle \) and \( \langle (m - \langle m \rangle)^2 \rangle \) with their errors using the program jack. The comments of the output of the command jack are removed with the command grep \(-v\). The fourth line is needed only for the calculation of the magnetic susceptibility, using equation \((13.30)\). There, we need to multiply the fluctuations \(\langle (m - \langle m \rangle)^2 \rangle\) and their error by the factor \( \beta N = \beta L^2 \) in order to obtain \( \chi \).
13.8.2 The Bootstrap Method

In this subsection we present a program for the calculation of the errors using the bootstrap method according to the discussion in section [13.6.3]. The program is in the file boot.f90:

```fortran
MODULE boot_function
  implicit none
SAVE
integer :: SAMPLES, MAXDAT
character(200) :: prog
integer :: seed
CONTAINS

! jackknife function:
  subroutine bootstrap(ndat, samples, x, &
    av0, er0, avchi, erchi)
    integer :: ndat, samples ! local samples...
    real(8), dimension(0:) :: x
    real(8) :: av0, er0, avchi, erchi
    integer :: i, j, k
    real(8), allocatable :: O(:), O2(:), chi(:)
    ALLOCATE(O(0: samples-1)); ALLOCATE(02(0: samples-1));
    ALLOCATE(chi(0: samples-1))
    DO j = 0, samples - 1
      DO i = 0, ndat - 1
        k = INT(ndat*drandom()) ! 0, ..., ndat - 1
        O(j) = O(j) + x(k)
        O2(j) = O2(j) + x(k)*x(k)
      ENDDO
      O(j) = O(j)/ndat; O2(j) = O2(j)/ndat
      chi(j) = O2(j) - O(j)*O(j)
    ENDDO
    av0 = SUM(0)/samples; avchi = SUM(chi)/samples
    er0 = sqrt(SUM((0 - av0 )*(0 - av0 ))/samples)
    erchi = sqrt(SUM((chi-avchi)*(chi-avchi))/samples)
  ! compute the real av0:
    av0 = SUM(x(0:ndat-1))/ndat
  DEALLOCATE(0); DEALLOCATE(chi)
end subroutine bootstrap

For the compilation we use the command

> gfortran -02 getopt.f90 boot.f90 -o boot
If our data is in one column in the file data, then the command that calculates the errors using 500 samples is:

```bash
> cat data | boot -s 500
```

The maximum number of measurements is set to 1,000,000 as in the jack program. For more measurements we should use the -d switch, e.g. for 2,000,000 measurements use `-d 2000000`. For the analysis of the magnetization from the output of the program is we can use the following command:

```bash
> is L 20 -b 0.4407 -s 1 -S 342 -n 2000000 | grep -v # | \ 
  awk -v L=20 '{print ($2>0)?($2/(L*L)):(-$2/(L*L))}' | \ 
  boot -s 1000 -d 2000000 | grep -v # | \ 
  awk -v b=0.4407 -v L=20 '{print ($2>0)?($2/(L*L)):(-$2/(L*L))}'
```

### 13.8.3 Comparing the Methods

In this subsection we will compute errors using equation (13.40), the jackknife method (13.43) and the bootstrap method (13.47). In order to appreciate the differences, we will use data with large autocorrelation times. We use the Metropolis algorithm on the Ising model with $L = 40$, $\beta = 0.4407 \approx \beta_c$, and measure the magnetization per site (13.28). We take 1,000,000 measurements using the commands:

```bash
> ./is -L 40 -b 0.4407 -s 1 -S 5434365 -n 1000000 \ 
  > outL40b0.4407.dat & \ 
> grep -v # outL40b0.4407.dat | \ 
  awk -v L=40 '{if($2<0){$2=-$2}; print $2/(L*L)}' \ 
  > outL40b0.4407.m \ 
> cat outL40b0.4407.m | autoc -t 10000 -n 1000000 \ 
  > outL40b0.4407.rhom
```

The file outL40b0.4407.m has the measurements of the magnetization in one column and the file outL40b0.4407.rhom has the autocorrelation function and the integrated autocorrelation time as described after page 548. We obtain $\tau_m = 286.3(3)$. The integrated autocorrelation time is found to be $\tau_{int,m} = 254(1)$.

The expectation value is $\langle m \rangle = 0.638682$. The application of equation (13.39), valid for independent measurements, gives the (underestimated) error $\delta_m = 0.00017$. Using equation (13.40) we obtain $\delta m =$
\( \sqrt{1 + 2\tau \delta_m} \approx 0.004 \). The error of the magnetic susceptibility cannot be calculated this way.

\[
\langle m \rangle = 0.639 \pm 0.004 \equiv 0.639(4) \quad (13.52)
\]

For the calculation of the error of the magnetic susceptibility we have

\[
\delta m_n \approx \frac{1}{n} \frac{S}{2}
\]

Figure 13.24: The error \( \delta m \) calculated using the bootstrap method as a function of the number of samples \( n_S \). We observe a very fast convergence to the value obtained by equation (13.39) \( \delta_m = 0.00017 \).

To resort to the jackknife or to the bootstrap method. The latter is applied initially using a variable number of samples \( n_S \) so that the optimal number of samples is be determined. Figure [13.24] shows the results for the magnetization. We observe a very fast convergence to \( \delta_m = 0.00017 \) for quite small number of samples. The analysis could have safely used \( n_S = 100 \). In the case of the magnetic susceptibility, convergence is slower, but we can still use \( n_S = 500 \). We obtain \( \chi = 20.39 \) and \( \delta_\chi = 0.0435 \). The error assumes independent measurements, something that is not true in our case. We should use the correction factor \( \sqrt{1 + 2\tau_m} \) which gives \( \delta_\chi = 1 \). Therefore

\[
\chi = 20 \pm 1 \equiv 20(1)
\quad (13.53)
\]

We note that the error is quite large, which is because we have few independent measurements: \( n/(2\tau_m) \approx 1,000,000/(2 \times 286) \approx 1750 \). The
Figure 13.25: The error $\delta \chi$ of the magnetic susceptibility calculated using the bootstrap method as a function of the number of samples $n_S$. We observe convergence for $n_S > 1000$ to the value $\delta_{c,\chi} = 0.0435$.

A priori knowledge of $\tau_m$ is necessary in this calculation. In the case of the jackknife method, the calculation can proceed without an a priori knowledge of $\tau_m$. The errors are calculated for a variable number of bins $n_b$. Figure [3.26] shows the results for the magnetization. When $n_b = n$ the samples consist of all the measurements except one. Then the error is equal to the error calculated using the standard deviation formula and it is underestimated by the factor $\sqrt{1 + 2\tau_m}$. This is shown in figure [3.26] where we observe a slow convergence to the value $\delta_{c,m} = 0.00017$. The effect of the autocorrelations vanishes when we delete (bin width) $\approx 2\tau_m$ measurements from each bin. This happens when $n_b \approx n/(\text{bin width}) = n/(2\tau_m) = 1,000,000/572 \approx 1750$. Of course this an order of magnitude estimate and a careful study is necessary in order to determine the correct value for $n_b$. Figure [3.26] shows that the error converges for $100 < n_b < 800$ to the value $\delta m = 0.0036$, which is quite close to the value $\sqrt{1 + 2\tau_m}\delta_{c,m} \approx 0.004$. We note that, by using a small number $n_b \approx 20-40$, we obtain an acceptable estimate, a rule of the thumb that can be used for quick calculations.

Similar results are obtained for the magnetic susceptibility $\chi$, where
the error converges to the value $\delta \chi = 0.86$, in accordance with the previous estimates. For $n_b \to n$ the error converges to the underestimated error $\delta_c \chi = 0.0421$.

We can use the bootstrap method, in a similar way to the jackknife method, in order to determine the real error $\delta m$, $\delta \chi$ without calculating $\tau_m$ directly. The data is split into $n_b$ bins, whose bin width is (bin width) $= n/n_b$. Each jackknife bin contains $n - n/n_b$ data elements and we apply the bootstrap method on this data, by taking $n_S$ samples of $n - n/n_b$ random data. Then each jackknife bin gives a measurement on which we apply equation (13.43) in order to calculate errors.

The above calculations can be reversed and used for the calculation of the autocorrelation time. By computing the underestimated error $\delta_c \mathcal{O}$ and the true error $\delta \mathcal{O}$ using one of the methods described above, we can...
calculate $\tau_m$ using the relation $\delta O / \delta_c O = \sqrt{1 + 2\tau_m \delta_c m}$. Therefore

$$\tau_m = \frac{1}{2} \left( \left( \frac{\delta m}{\delta_c m} \right)^2 - 1 \right) = \frac{1}{2} \left( \left( \frac{\delta \chi}{\delta_c \chi} \right)^2 - 1 \right) = \ldots$$ (13.54)

By calculating $\tau_m$ using all the methods described here, these relations can also be used in order to check the analysis for self-consistency and see if they agree. This is not always a trivial work since a system may have many autocorrelation times which influence each observable in a different way (fast modes, slow modes).

### 13.9 Problems

1. Prove that equation (13.22) satisfies the detailed balance condition.

2. Write a program that prints the memory used by variables of the type character, integer, integer(8), real, real(8) in bytes. Calculate the amount of memory needed for an array of size 2,000,000 for each of the above types of variables.
13.9. PROBLEMS

3. Make the appropriate changes in the Ising model program so that it measures the average acceptance ratio $\hat{A}$ of the Metropolis steps. I.e. compute the ratio of accepted spin flips to the number of attempted spin flips. Compute the dependence of $\hat{A}$ on the temperature and the size of the system. Take $L = 20$ and $\beta = 0.20, 0.30, 0.40, 0.42, 0.44, 0.46, 0.48, 0.50$. Then take $\beta = 0.20, L = 10, 20, 40, 80, 100$. Repeat for the same values of $L$ for $\beta = 0.44$ and $\beta = 0.48$.

4. Reproduce the plots in figure 13.12 and compute $\tau_m$. Repeat for $\tau_e$. Compare your results with $\tau_{int,m}$ and $\tau_{int,e}$.

5. Reproduce the plots in figure 13.15 and repeat your calculation for the energy.

6. Reproduce the plots in figure 13.17. Repeat your calculation for the energy. Then, construct similar plots for $\tau_{int,m}$ and $\tau_{int,e}$ as a function
Figure 13.29: Figure 13.28 magnified in the region of the plateau in the values of $\delta \chi$. Convergence is observed for $100 < n_b < 800$ to $\delta \chi = 0.86$. The values $\delta \chi$ and $\delta_c \chi$ are shown in the plots by the two horizontal lines. The ratio $\delta \chi / \delta_c \chi \approx \sqrt{1 + 2T_m}$.

7. Reproduce the plots in figures 13.19 and 13.20. Repeat your calculation for the energy. Then, construct similar plots for $\tau_{\text{int},m}$ and $\tau_{\text{int},e}$ as a function of $t_{\text{max}}$ (see figure 13.14).

8. Modify the Ising model program presented in the text so that it can simulate the Ising model in the presence of an external magnetic field $B$ (see equation (13.2)). Calculate the magnetization per site $m(\beta, B)$ for $L = 32$ and $B = 0.2, 0.4, 0.6, 0.8, 1.0$ at an interesting range of temperatures. Use different initial configuration in order to study the thermalization of the system as $B$ increases: Cold state with spins parallel to $B$, cold state with spins antiparallel to $B$ and hot state. Study the dependence of the critical temperature separating the ordered from the disordered state on the value of $B$.

9. Hysteresis: In the previous problem, the Ising model with $B \neq 0$ has a first order phase transition, i.e. a discontinuity in the value of the order parameter which in our case is the magnetization as a function
13.9. PROBLEMS

of $B$. Near a first order transition we observe the phenomenon of hysteresis. In order to see it, set $L = 32$ and $\beta = 0.55$ and

(a) thermalize the system for $B = 0$

(b) simulate the system for $B = 0.2$ using as an initial state the last one coming from the previous step. Do 100 sweeps and calculate $\langle m \rangle$.

(c) continue by increasing each time the magnetic field by $\delta B = 0.2$. Stop when $\langle m \rangle \approx 0.95$.

(d) using the last configuration from the previous step, repeat by decreasing the magnetic field by $\delta B = -0.2$ until $\langle m \rangle \approx -0.95$.

(e) using the last configuration from the previous step, repeat by increasing the magnetic field by $\delta B = 0.2$ until $\langle m \rangle \approx 0.95$.

Make the plot $(B, m)$. What do you observe?

For systems near a first order phase transition, the order parameter can take two different values with almost equal probability. This means that the free energy has two local minima. Only one of them is the true, global minimum. This is depicted in figure 12.2 where two equally probable values of the order parameter are shown. This happens exactly at the critical point. When we move away from the critical point, one of the peaks grows and it is favored corresponding to the global minimum of the free energy. The local minimum is called a metastable state and when the system is in such a state, it takes a long time until a thermal fluctuation makes it overcome the free energy barrier and find the global minimum. In a Monte Carlo simulation such a case presents a great difficulty in sampling states correctly near the two local minima. Repeat the above simulations, this time making 100,000 sweeps per point. Plot the time series of the magnetization and observe the transitions from the metastable state to the stable one and backwards. Compute the histogram of the values of the magnetization and determine which state is the metastable in each case. How is the histogram changing as $B$ is increased?

10. Write a program that simulates the 2 dimensional Ising model on a triangular lattice using the Metropolis algorithm. The main difference is that the number of nearest neighbors is $z = 6$ instead of $z = 4$. Look into chapter 13.1.2 of Newman and Barkema (esp. figure 13.4). Compute the change in energy for each spin flip for the
CHAPTER 13.  \( D = 2 \) ISING MODEL

Metropolis step. Calculate the maxima of the magnetic susceptibility and of the specific heat and see if they are close to the expected critical temperature \( \beta_c \approx 0.274653072 \). Note that even though \( \beta_c \) is different than the corresponding value on the square lattice, the critical exponents are the same due to universality.

11. Write a program that simulates the three dimensional Ising model on a cubic lattice using the Metropolis algorithm. Use helical boundary conditions (all you need in this case is to add a parameter \( ZNN = L \times L \) together with the \( XNN = 1 \) and \( YNN = L \)).

12. Write a program that simulates the three dimensional Ising model on a cubic lattice using the Metropolis algorithm. Use periodic boundary conditions. (Hint: Use a one dimensional array \( s(N) \). During initialization, compute the arrays \( XNN(-N:N), \ YNN(-N:N), \ ZNN(-N:N) \) which store the nearest neighbors of the position \( i \) on the lattice in \( XNN(i), XNN(-i), YNN(i), YNN(-i), ZNN(i), ZNN(-i) \).)

13. Simulate the antiferromagnetic two dimensional Ising model on a square lattice using the Metropolis algorithm. You may use the same code that you have and enter negative temperatures. Find the ground state(s) of the system.

Define the staggered magnetization \( m_s \) to be the magnetization per site of the sublattice consisting of sites with odd \( x \) and \( y \) coordinate. Set \( L = 32 \) and compute the energy, the \( m_s \), the specific heat, the magnetic susceptibility \( \chi \) and the staggered magnetic susceptibility \( \chi_s = \beta N / 4 \langle (m_s - \langle m_s \rangle)^2 \rangle \).

\( \chi \) has a maximum in the region \( \beta \approx 0.4407 \). Compute its value at this temperature for \( L = 32 - 120 \). Show that \( \chi \) does not diverge as \( L \to \infty \), therefore \( \chi \) does not show a phase transition.

Repeat the calculation for \( \chi_s \). What do you conclude? Compare the behavior of \( \langle m_s \rangle \) for the antiferromagnetic Ising model with \( \langle m \rangle \) of the ferromagnetic.

14. Modify the program in boot.f90 so that it bins its input data. Reproduce the plots in figures ?? and ?? . (Hint: See the file boot.bin.f90)
Figure 13.30: Horizontal motion on the $L = 5$ square lattice with periodic boundary conditions. The trajectory is a circle.
Figure 13.31: Horizontal motion on the $L = 5$ square lattice with helical boundary conditions. The trajectory is a spiral.
Figure 13.32: Spin configurations for the Ising model with $L = 400$, $\beta = 0.4292$ after 4000, 9000, 12000 and 45000 sweeps respectively. We observe the formation of large clusters of same spin. This makes hard to form a new independent configuration with the Metropolis algorithm and results in large autocorrelation times.
Chapter 14

Critical Exponents

In the previous chapters, we saw that when a system undergoes a continuous phase transition as \( \beta \to \beta_c \), or equivalently as the reduced temperature \( t \equiv \frac{\beta_c - \beta}{\beta_c} \to 0 \), \( (14.1) \)
the correlation length \( \xi \equiv \xi(\beta, L = \infty) \), calculated in the thermodynamic limit diverges according to the relation
\[
\xi \sim |t|^{-\nu} \quad (\nu = 1 \text{ for 2d-Ising}) \quad (14.2)
\]
The behavior of such systems near the phase transition is characterized by critical exponents, such as the exponent \( \nu \), which are the same for all systems in the same universality class. The critical exponents describe the leading non analytic behavior of the observables in the thermodynamic limit \( L \to \infty \), when \( t \to 0 \). Systems with the same long distance behavior, but which could possibly differ microscopically, belong to the same universality class. For example, if we add a next to nearest neighbor interaction in the Hamiltonian of the Ising model or if we consider the system on a triangular instead of a square lattice, the system will still belong to the same universality class. As \( \xi \to \infty \) these details become irrelevant and all these systems have the same long distance behavior. Microscopic degrees of freedom of systems in the same universality class can be quite different, as is the case of the liquid/vapor phase transition at the triple point and the Ising model.

\^You may also find the definition \( t = (T - T_c)/T_c \) but as \( t \ll 1 \) the two definitions are almost equivalent (they differ by a term of order \( \sim t^2 \)).

\^Beware: We first take \( L \to \infty \) and then \( t \to 0 \).
CHAPTER 14. CRITICAL EXponents

The critical exponents of the 2d Ising model universality class are the Onsager exponents:

\[ \chi \sim |t|^{-\gamma} \quad \gamma = 7/4, \]  
\[ c \sim |t|^{-\alpha} \quad \alpha = 0 \quad \text{and} \]  
\[ \langle m \rangle \sim |t|^\beta \quad t < 0, \quad \beta = 1/8. \]  

This behavior is seen only in the thermodynamic limit \( L \to \infty \). For a finite lattice, all observables are analytic since they are calculated from the analytic partition function \( Z(\beta) \) given by equation (13.4). When \( 1 \ll \xi \ll L \) the model behaves approximately as the infinite system. As \( \beta \approx \beta_c \) and \( \xi \sim L \) finite size effects dominate. Then the fluctuations, e.g. \( \chi \) and \( c \), on the finite lattice have a maximum for a pseudocritical temperature \( \beta_c(L) \) for which we have that

\[ \lim_{L \to \infty} \beta_c(L) = \beta_c. \]  

For the Ising model on the square lattice, defined by (13.14), we have that \( \beta_c = \log(1 + \sqrt{2})/2. \)

Because of (14.2), when on the finite lattice we take \( \beta = \beta_c(L) \), we have that \( \xi(t, L) \sim L \Rightarrow |t| = |(\beta_c - \beta_c(L))/\beta_c| \sim L^{-1/\nu} \), therefore equations (14.3)–(14.5) become

\[ \chi \sim L^{\gamma/\nu}, \]  
\[ c \sim L^{\alpha/\nu}, \]  
\[ \langle m \rangle \sim L^{-\beta/\nu}. \]  

The left hand sides of the above relations are normally evaluated at \( \beta = \beta_c(L) \), but they can also be evaluated at any temperature in the pseudocritical region. Most of the times, one calculates the observables for \( \beta = \beta_c(L) \), but one can also use e.g. \( \beta = \beta_c \). In the next sections we will show how to calculate the critical exponents by using the scaling relations (14.3)–(14.5) and (14.7)–(14.9).

\( ^1 \) It is a finite sum of analytic functions, therefore an analytic function.

\( ^2 \) Each observable may have a slightly different pseudocritical temperature, so we may write \( \beta_\xi(L), \beta_\gamma(L) \) etc.

\( ^3 \) In the limit \( L \to \infty \) the difference is not important, it comes from analytic terms which don’t contribute to the non analytic behavior. In practice, the speed of convergence to the asymptotic behavior may differ.
14.1 Critical Slowing Down

The computation of critical exponents is quite involved and requires accurate measurements, as well as simulations of large systems in order to reduce finite size effects. The Metropolis algorithm suffers from severe critical slowing down, i.e. diverging autocorrelation times with large dynamic exponent \( z \) according to (13.36), near the critical region, which makes it impossible to study large systems. In this section we will discuss the cause of this effect whose understanding will lead us to new algorithms that beat critical slowing down. These are the cluster algorithms and, in particular, the Wolff algorithm. The success of these algorithms is based on the dynamics of the system and, therefore, they have a more specialized range of applications. In contrast, the Metropolis algorithm can, in principle, be applied on any system studied with the Monte Carlo method.

According to the discussion in section 13.5, the Ising model simulation using the Metropolis algorithm near the critical region exhibits an increase in autocorrelation times given by the scaling relation (13.36)

\[ \tau \sim \xi^z. \] (14.10)

The correlation length of the finite system becomes \( \xi \sim L \) in this region, and we obtain equation (13.36), \( \tau \sim L^z \). When \( z > 0 \) we have the effect of critical slowing down.

Critical slowing down is the main reason that prohibits the simulation of very large systems, at least as far as CPU time \( t_{CPU} \) is concerned.\(^6\) The generation of a given number of configuration requires an effort \( t_{CPU} \sim L^d \). But the measurement of a local quantity, like \( \langle m \rangle \), for a given number of times requires no extra cost, since each configuration yields \( L^d \) measurements.\(^7\) In this case, measuring for the largest possible \( L \) is preferable, since it reduces finite size effects. We see that, in the absence of critical slowing down, the cost of measurement of \( \langle m \rangle \) is \( t_{CPU}^{(m)} \sim L^0 \).

Critical slowing down, however, adds to the cost of production of independent configurations and we obtain \( t_{CPU}^{(m)} \sim L^z \), making the large \( L \) simulations prohibitively expensive. For the Metropolis algorithm on the two dimensional Ising model we have that \( z \approx 2.17 \); and the problem is severe. Therefore, it is important to invent new algorithms that beat critical slowing down. In the case of the Ising model and similar

---

\(^6\)Of course the amount of available memory can be another inhibiting factor.

\(^7\)Each site contributes one measurement!
spin systems, the solution is relatively easy. It is special to the specific
dynamics of spin systems and does not have a universal application.

The reason for the appearance of critical slowing down is the diver-

gence of the correlation length $\xi$. As we approach the critical temperature
$\beta \to \beta_c$ from the disordered phase, the typical configurations are domi-
nated by large clusters of same spins. The Metropolis algorithm makes
at most one spin flip per step and the acceptance ratios for spins inside
a cluster are small. For example, a spin with four same neighboring
spins can flip with probability $e^{-8\beta_c} \approx 0.029$, which is quite small. The
spins that change more often are the ones with more neighbors having
opposite spins, therefore the largest activity is observed at the bound-
aries of the large clusters. In order to obtain a statistically independent
configuration, we need to destroy and create many clusters, something
that happens very slowly using the Metropolis algorithm who realizes
this process mostly by moving the boundaries of the clusters.

14.2 Wolff Cluster Algorithm

Beating critical slowing down requires new algorithms so that at each
step a spin configuration is changed at the scale of a spin cluster. The
cluster algorithms construct such regions of same spins in a way that the
proposed new configuration has all the spins of the clusters flipped. For
such an algorithm to be successful, the acceptance ratios should be large.
The most famous ones are the Swendsen-Wang and the Wolff cluster algo-

rithms.

The process of constructing the clusters is stochastic and depends on
the temperature. Small clusters should be favored for $\beta \ll \beta_c$, whereas
large clusters of size $L$ should dominate for $\beta \gg \beta_c$.

The basic idea of the Wolff algorithm is to choose a site randomly, a so
called seed of the cluster, and construct a spin cluster around it. At each
step, we add new members to the cluster with probability $P_{\text{add}} = P_{\text{add}}(\beta)$.
If $P_{\text{add}}(\beta)$ is properly chosen, the detailed balance condition (12.59) is
satisfied and the new configuration is always accepted. This process is
depicted in figure 14.1. In the state $\mu$, the cluster is enclosed by the
dashed line. The new state $\nu$ is obtained by flipping all the spins in the
cluster, leaving the rest of the spins to be the same.

---

*A spin cluster is a subset of the lattice composed of connected lattice sites of same spins.*
The correct choice of $P_{\text{add}}$ will yield equation (12.60)

$$\frac{P(\mu \rightarrow \nu)}{P(\nu \rightarrow \mu)} = e^{-\beta(E_\nu - E_\mu)}. \quad (14.11)$$

The discussion that follows proves (14.11) and can be found in the book by Newman and Barkema [4]. The crucial observation is that the change in energy in the exponent of the right hand side of (14.11) is due to the creation/destruction of bonds on the boundary of the cluster. The structure of the bonds in the interior of the cluster is identical in the two configurations $\mu$ and $\nu$. This can be seen in the simple example of figure 14.1. By properly choosing the selection probability $g(\mu \rightarrow \nu)$ of the new state $\nu$ and the acceptance ratio $A(\mu \rightarrow \nu)$, so that

$$P(\mu \rightarrow \nu) = g(\mu \rightarrow \nu) A(\mu \rightarrow \nu), \quad (14.12)$$

we will succeed in satisfying (14.11) and maximize the acceptance ratio. In fact in our case we will find that $A(\mu \rightarrow \nu) = 1$!

The selection probability $g(\mu \rightarrow \nu)$ is the probability of constructing a particular cluster and can be split in three factors:

$$g(\mu \rightarrow \nu) = p_{\text{seed}} \times p_{\text{yes}}^{\text{int}} \times p_{\text{no}}^{\text{border}}. \quad (14.13)$$

The first term is the probability to start the cluster from the particular seed. By choosing a lattice site with equal probability we obtain

$$p_{\text{seed}} = \frac{1}{N}. \quad (14.14)$$
Then the cluster starts growing around its seed. The second term $p^\text{int}_{\text{yes}}$ is the probability to include all cluster members found in the interior of the cluster. This probability is complicated and depends on the size and shape of the cluster. Fortunately, it is not important to calculate it. The reason is that in the opposite transition $\nu \to \mu$, the corresponding term is exactly the same since the two clusters are exactly the same (the only differ by the value of the spin)!

$$p^\text{int}_{\text{yes}}(\mu \to \nu) = p^\text{int}_{\text{yes}}(\nu \to \mu) \equiv C_{\mu\nu}. \quad (14.15)$$

The third term is the most interesting one. The cluster stops growing when we are on the boundary and say “no” to including all nearest neighbors with same spins, which are not already in the cluster (obviously, the opposite spins are not included). If $P_{\text{add}}$ is the probability to include a nearest neighbor of same spin to the cluster, the probability of saying “no” is $1 - P_{\text{add}}$. Assume that we have $m$ “bonds”\footnote{A link with same spins on both sides.} of same spins on the boundary of the cluster in the state $\mu$, and that we have $n$ such bonds in the state $\nu$. In figure 14.1, for example, we have that $m = 5$ and $n = 7$. Therefore, the probability to stop the cluster in the state $\mu$ is to say “no” $m$ times, which happens with probability $(1 - P_{\text{add}})^m$:

$$p^\text{border}_{\text{no}}(\mu \to \nu) = (1 - P_{\text{add}})^m. \quad (14.16)$$

Similarly, the cluster in the state $\nu$ stops at the same boundary with probability

$$p^\text{border}_{\text{no}}(\nu \to \mu) = (1 - P_{\text{add}})^n. \quad (14.17)$$

Therefore

$$\frac{P(\mu \to \nu)}{P(\nu \to \mu)} = \frac{\frac{1}{N} C_{\mu\nu} (1 - P_{\text{add}})^m A(\mu \to \nu)}{\frac{1}{N} C_{\mu\nu} (1 - P_{\text{add}})^n A(\nu \to \mu)} = e^{-\beta(E_{\nu} - E_{\mu})}. \quad (14.18)$$

The right hand side of the above equation depends only on the number of bonds on the boundary of the cluster. The energy difference depends only on the creation/destruction of bonds on the boundary of the cluster and the internal bonds don’t make any contribution to it. Each bond created during the transition $\mu \to \nu$ decreases the energy by 2 and each bond destroyed increases the energy by 2:

$$E_{\nu} - E_{\mu} = (-2n) - (-2m) = 2(m - n). \quad (14.19)$$
which yields
\[
(1 - P_{\text{add}})^{m-n} \frac{A(\mu \to \nu)}{A(\nu \to \mu)} = e^{-2\beta(m-n)} \Rightarrow \frac{A(\mu \to \nu)}{A(\nu \to \mu)} = e^{2\beta(1 - P_{\text{add}})}^{n-m}.
\]
From the above relation we see that if we choose
\[
1 - P_{\text{add}} = e^{-2\beta} \Rightarrow P_{\text{add}} = 1 - e^{-2\beta},
\]
then we can also choose
\[
A(\mu \to \nu) = A(\nu \to \mu) = 1!
\]
Therefore, we can make the condition (14.11) to hold by constructing a cluster using the \( P_{\text{add}} \) given by (14.21), flipping its spins, and always accepting the resulting configuration as the new state.

Summarizing, the algorithm for the construction of a Wolff cluster consists of the following steps:

1. Choose a seed by picking a lattice site with probability \( p_{\text{seed}} = \frac{1}{N} \). This is the first new member of the cluster
2. Repeat: For each new member of the cluster, visit its nearest neighbors that do not already belong to the cluster. If they have the same spin, add them to the “new members” of the cluster with probability \( P_{\text{add}} \). The original spin is not a “new member” anymore
3. When there are no more “new members”, the construction of the cluster ends
4. Flip the spin of all the members of the cluster.

The algorithm is ergodic, since every state can be obtained from any other state by constructing a series of clusters of size 1 (equivalent to single flips).

The probability \( P_{\text{add}} \) depends on the temperature \( \beta \). It is quite small for \( \beta \ll \beta_c \) and almost 1 for \( \beta \gg \beta_c \). Therefore, in the first case the algorithm favors very small clusters (they are of size 1 for \( \beta = 0 \)) and in the second case it favors large clusters. In the high temperature regime, we have almost random spin flips, like in the Metropolis algorithm. In the low temperature regime, we have large probability of flipping the dominant cluster of the lattice. This is clearly seen in figure 14.2, where the fraction of the average cluster size to the lattice size \( \langle n \rangle / N \) is plotted...
as a function of the temperature. For small $\beta$, $\langle n \rangle / N \to 1/N$ whereas for large $\beta$, $\langle n \rangle / N \to 1$.

Figure 14.3 shows typical spin configurations in the high and low temperature regimes. For small $\beta$, most of the time the algorithm chooses a lattice site randomly and constructs a small cluster around it and flips its spins. The Metropolis algorithm picks a lattice site randomly and flips it most of the times. In both cases, the two algorithms function almost the same way and construct the high temperature disordered spin configurations. For large $\beta$, a typical spin configuration is a “frozen” one: A large cluster of same spins with a few isolated thermal fluctuations of different spins. Most of the times, the Wolff algorithm picks a seed in the dominant cluster and the new cluster is almost the same as the dominant cluster: Most of its sites are included with few ones excluded, which upon flipping of the spins, they will form the new thermal fluctuations. After the flips, the old thermal fluctuations have the same spin as the dominant cluster and they become part of the new dominant cluster. The Metropolis algorithm picks lattice sites randomly: When they belong to the dominant cluster they are seldomly flipped, whereas
14.2. WOLFF CLUSTER ALGORITHM

Figure 14.3: A typical spin configuration in the disordered phase (left, $\beta = 0.25$) and in the ordered phase (right, $\beta = 0.5556$) for the Ising model on the square lattice for $L = 100$.

the thermal fluctuations are flipped most of the time. Both algorithms function similarly and have the same efficiency.

Figure 14.4: Two typical spin configurations in the (pseudo)critical region ($\beta = 0.4348$) for the Ising model on the square lattice for $L = 100$. The two configurations differ by 5000 Metropolis steps.

Figure 14.4 shows typical spin configurations in the critical region. These are dominated by large clusters whose size, shape and position are random. The Wolff algorithm constructs large clusters easily, therefore, large clusters are easily created and destroyed in a few steps (figure 14.2 shows that $\langle n \rangle / N \approx 0.5$). In contrast, the Metropolis algorithm modifies clusters by slowly moving their boundaries and large clusters are destroyed/created very slowly. Autocorrelation times are expected to
reduce drastically when using the Wolff algorithm in the critical region.

The expectation value of the size of the Wolff clusters is a dynamical quantity. In order to see this, we will show that in the disordered phase ($\beta < \beta_c$) we have that

$$\chi = \beta \langle n \rangle . \quad (14.23)$$

We take the discussion from Newmann and Barkema [4]: Create a bond on each link of the lattice connecting two same spins with probability $P_{\text{add}} = 1 - e^{-2\beta}$. In the end, the lattice will be divided in $N$ Wolff clusters. Each one will consist of $n_i$ sites, whose spin is $S_i$. Choose a lattice site randomly and flip the spins of the cluster it belongs to. Destroy the bonds and repeat the process. The total magnetization is:

$$M = \sum_{i=1}^{N_c} S_i n_i , \quad (14.24)$$

and

$$\langle M^2 \rangle = \left( \sum_{i=1}^{N_c} S_i n_i \right) \left( \sum_{j=1}^{N_c} S_j n_j \right) = \langle \sum_{i \neq j} S_i S_j n_i n_j \rangle + \langle \sum_i S_i^2 n_i^2 \rangle . \quad (14.25)$$

The values $S_i = \pm 1$ are equally probable due to the symmetry of the model, therefore the first term vanishes. Since $S_i^2 = 1$, we obtain

$$\langle m^2 \rangle = \frac{1}{N^2} \langle M^2 \rangle = \frac{1}{N^2} \langle \sum_i n_i^2 \rangle . \quad (14.26)$$

In the Wolff algorithm, the creation of a cluster is equivalent to the choice of one of the clusters we created by following the procedure described above. The probability of selecting the cluster $i$ is

$$p_i = \frac{n_i}{N} , \quad (14.27)$$

therefore the average value of the size of the Wolff clusters will be

$$\langle n \rangle = \langle \sum_i p_i n_i \rangle = \langle \sum_i \frac{n_i}{N} n_i \rangle = N \langle m^2 \rangle . \quad (14.28)$$

\[10\] These are true Wolff clusters since the bonds have been activated with the correct probability. There are of course isolated sites with no activated bonds around them which are Wolff clusters of size 1.

\[11\] The result is equivalent to performing one step of the Wolff algorithm, not a very efficient one of course...
By using equation \(14.26\) and the fact that for \(\beta < \beta_c\) we have that \(\langle m \rangle = 0\) therefore
\[
\chi = \beta N (\langle m^2 \rangle - \langle m \rangle^2) = \beta \langle n \rangle. \quad (14.29)
\]

### 14.3 Implementation

In order to create a cluster around a seed, we need a memory buffer for storing the new members of the cluster. We draw cluster sites from this buffer, and examine whether to add their nearest neighbors to the cluster.

There are two data structures that can be used in this job. The first one is the stack (or LIFO: last in – first out) and the second one is the queue (or FIFO: first in – first out). They are both one dimensional arrays, the only difference is how we draw data from them. In the case of a stack, we draw the last element that we stored in it. In the case of the queue, we draw the first element that we stored in it.

The stack is implemented as a one dimensional array \(\text{stack}(0:N-1)\) in which we “push” a new value that we want to store and we “pop” one that we want to retrieve. We use an integer \(m\) as a pointer to the last value that we stored in the position \(\text{stack}(m-1)\). \(m\) is also the number of active elements in the stack. In order to push a value \(e\) into the stack we:

1. check if there exist available positions in the stack (i.e. if \(m<N\))
2. set \(\text{stack}(m) = e\)
3. increase \(m\) by 1.

In order to pop a value and store it in the variable \(e\) we:

1. check if the stack is non empty (i.e. if \(m>0\))
2. reduce \(m\) by 1
3. set \(e = \text{stack}(m)\)

The queue implementation is different. The data topology is cyclic, as shown in figure [14.5]. We use an array \(\text{queue}(0:N-1)\) and two integers \(m, n\) which point at the beginning and at the end of the buffer. The

---

\(^{12}\) This is exactly true only in the thermodynamics limit. For a finite lattice of size \(N\), the two quantities differ by a factor of \(\beta N \langle m \rangle^2 > 0\), which vanishes in the large \(N\) limit.

\(^{13}\) \(\text{stack}(0:N-1)\) defines an array with elements \(\text{stack}(0), \text{stack}(1), ..., \text{stack}(N-1)\)
beginning of the data is the element queue(m-1) and the end of the data is the element queue(n). When the queue is empty, we have that m=n and the same is true when it is full. Therefore we need a flag that flags whether the queue is empty or full. In the beginning we set flag=0 (queue is empty). The number \((m-n) \mod N\) is the number of stored elements. When the queue has data, we set flag=1. In order to store a value \(e\) into the queue we:

1. check whether the queue is full \((m=n\) and \(flag=1\))
2. set \(flag=1\)
3. set queue(m) = \(e\)
4. increase \(m\) by 1 \(\mod N\).

In order to pop a value and store it in the variable \(e\) we:

1. check whether the queue is empty \((m=n\) and \(flag=0\))
2. set \(e = queue(n)\)
3. increase \(n\) by 1 \(\mod N\).

\[^{14}\text{If we choose to store at most } N-1 \text{ elements in } queue(N) \text{ then the algorithm becomes slightly simpler (exercise).}\]

\[^{15}\text{Except if } m=n \text{ in which case the number of stored elements is 0 or } N \text{ according to the value of } flag.\]
4. if \( m=n \) set \( \text{flag}=0 \).

Summarizing, the algorithm for constructing a Wolff cluster for the Ising model is the following:

1. choose a seed by randomly picking a site with probability \( 1/N \)

2. check its nearest neighbors. If they have the same spin, add them to the cluster with probability \( P_{\text{add}} = 1 - e^{-2\beta} \). The new members of the cluster are pushed into the stack \( \text{stack}(0:N-1) \) according to the previous discussion

3. pop a site from the stack \( \text{stack}(0:N-1) \). If the stack is empty we stop the construction and move on to the next step. If not, we check the site’s nearest neighbors. If they are not already in the cluster and they have the same spin, we add them to the cluster with probability \( P_{\text{add}} \)

4. record the size of the cluster and flip the spin of its members.

The choice between stack or queue is not important. The results are the same and the performance similar. The only difference is the way that the clusters are constructed (for the stack, the cluster increases around the seed whereas for the queue it increases first in one direction and then in another). The careful programmer will try both during the debugging phase of the development. Bad random number generators can be revealed in such a test, since the Wolff algorithm turns out to be sensitive to their shortcomings.

### 14.3.1 The Program

The heart of the algorithm is coded in the subroutine \( \text{wolff()} \) in the file \( \text{wolff.f90} \). Each call to \( \text{wolff()} \) constructs a Wolff cluster, flips its spin and records its size.

The buffer \( \text{stack}(0:N-1) \) is used in order to store the new members of the cluster. We call the function \( \text{ALLOCATE} \) for dynamically allocating the necessary memory and use \( \text{DEALLOCATE} \) before returning to the calling program in order to return this memory back to the system - and avoid memory leaks.

\[ \text{It is essentially the program in the book by Newman and Barkema [3].} \]
If the requested memory is not available, then \( \text{chk} > 0 \) and the subroutine \( \text{locerr}() \) stops the program.

The seed is chosen randomly by a call to \( \text{ranlux} \):

\[
\begin{align*}
\text{call} & \text{ ranlux}(r,1) \\
cseed & = \text{INT}(N*r)+1 \\
\text{stack}(0) & = \text{cseed} \\
nstack & = 1 \quad \text{!the stack has } 1 \text{ member, the seed} \\
sold & = s(cseed) \quad \text{!the new spin value of the cluster} \\
snew & = -s(cseed) \quad \text{!we flip all new members of cluster} \\
s(cseed) & = snew \\
ncluster & = 1 \quad \text{!size of cluster}=1
\end{align*}
\]

The seed is stored in \( \text{cseed} \) which is immediately added to the cluster \( \text{stack}(0)=\text{cseed} \). The variable \( \text{nstack} \) records the number of elements in the stack and it is originally set equal to 1. The variable \( \text{ncluster} \) counts the number of sites in the cluster and it is originally set equal to 1. \( \text{sold} = s(cseed) \) is the old value of the spin of the cluster and \( \text{snew} = -\text{sold} \) is the new one. The value of the spin of a new member of the cluster is immediately changed \( (s(cseed)=\text{snew}) \). This increases the efficiency of the algorithm. By checking whether the spin of a nearest neighbor is equal to \( \text{sold} \), we check whether the spin is the same as that of the cluster and if it has already been included in the cluster during a previous check.

The loop over the new members of the cluster is summarized below:

\[
\begin{align*}
\text{do while}(\text{nstack} > 0) & \\
!\text{pull a site off the stack:} \\
\text{nstack} & = \text{nstack} - 1; \text{scluster} = \text{stack(nstack)} \\
!\text{check its four neighbors:} \\
\text{-----------scluster} + \text{XNN:} \\
nn & = \text{scluster} + \text{XNN}; \text{if}(\text{nn} > N) \text{nn} = \text{nn} - N \\
\text{if}(s(\text{nn}) == \text{sold}) & \text{then} \\
\text{call} & \text{ ranlux}(r,1) \\
\text{if}(r<\text{padd}) & \text{then} \\
\text{stack}(\text{nstack}) & = \text{nn}; \text{nstack} = \text{nstack} + 1 \\
\text{s(\text{nn})} & = \text{snew} \\
\text{ncluster} & = \text{ncluster}+1 \\
\text{endif} \\
\text{endif} \\
\text{endif}
\end{align*}
\]
The loop do while(nstack > 0) is executed while nstack>0, i.e. as long as the stack is not empty and there exist new members in the cluster. The variable scluster is the current site drawn from the stack in order to check its nearest neighbors. The line nn = scluster + XNN; if(nn > N) nn = nn - N chooses the nearest neighbor to the right and stores it in the variable nn. If the spin s(nn) of nn is equal to sold, then this neighbor has the same spin as that of the cluster and it has not already been included to the cluster (otherwise its spin would have been flipped). The variable padd is equal to $P_{\text{add}}$ (it has been set in init) and if $r<padd$ (which happens with probability $P_{\text{add}}$), then we add nn to the cluster: We add nn to the stack, we flip its spin ($s(\text{nn})=s\text{new}$) and increase the cluster size by 1. We repeat for the rest of the nearest neighbors. The full code is listed below:

```fortran
 subroutine wolff
  use global_data
  implicit none
  integer :: cseed, nstack, sold, snew, scluster, nn, chk
  integer :: ncluster
  real(8) :: r
  integer, allocatable :: stack(:)

  allocate(stack(0:N1), STAT=chk)
  if(chk>0) call locerr('allocation failure for stack in wolff')
  !choose a seed for the cluster, put it on the stack and flip it
  call ranlux(r,1)
  cseed = INT(N*r)+1
  stack(0) = cseed
  nstack = 1   ! the stack has 1 member, the seed
  sold = s(cseed)
  snew = -s(cseed)   ! the new spin value of the cluster
  s(cseed) = snew   ! we flip all new members of cluster
  ncluster = 1   ! size of cluster=1

  ! start the loop on spins in the stack:
  do while(nstack > 0)
    ! pull a site off the stack:
    nstack = nstack - 1; scluster = stack(nstack)
    ! check its four neighbors:
    do nn = scluster + XNN: if(nn > N) nn = nn - N
      if(s(nn) == sold) then
        call ranlux(r,1)
        if(r<padd) then
          ! ... check other 3 nearest neighbors ...
          enddo
    enddo
  enddo
```

![... check other 3 nearest neighbors ...](image-url)
In order to link the subroutine with the rest of the program so that we construct one cluster per "sweep", we modify main() accordingly:

[Beware: A Metropolis sweep is not the same as a cluster update. The average size of the cluster changes with $\beta$ and it is quite small for large temperatures (small $\beta$).]
The (global) variable `algorithm` controls whether the Wolff or the Metropolis algorithm will be used for the spin updates. The (global) variable `padd` is defined in `init()`. The following lines are added: into the file `global_data.f90`

```fortran
real(8) :: padd
integer :: algorithm
```

The following lines are added to the file `init.f90`

```fortran
algorithm=0
!default is metropolis, 1 is wolff
padd = 1.0D0 - exp(-2.0D0*beta)
```

The following lines are added to the file `options.f90`

```fortran
select case(getopt("-hL:b:s:n:r:uw"))
  case ("w")
    algorithm = 1
  ....
```

in order to add the option `-w` to the command line. This option sets `algorithm=1`, which makes the program run the Wolff algorithm instead of the Metropolis. Some extra info must also be added to the help mes-

\]

do the compilation, print the usage instructions of the program and perform a test run for \( L = 40, \ \beta = 0.44, \) by constructing 5000 clusters, starting from a hot configuration and writing the data to the file outL20b0.44.

\subsection{14.4 Production}

In order to study the Ising model on a square lattice of given size \( N, \) we have to perform simulations for many values of \( \beta. \) Then, we want to study the finite size properties and extrapolate the results to the thermodynamic limit, by repeating the process for several values of \( N. \) The process is long and ... boring. Moreover, a bored researcher makes mistakes and several bugs can enter into her calculations. Laziness is a virtue in this case and it is worth the trouble and the time investment in order to learn some techniques that will make our life easier, our work more
efficient, and our results more reliable. Shell scripting can be used in order to code repeated tasks of the command line. In its simplest form, it is just a series of commands written into a text file. Such an example can be found in the file `run1`:

```
# ################################################################### run1 ###################################################################
./is -L 20 -b 0.10 -s 1 -n 5000 -w -S 3423 > outL20b0.10
./is -L 20 -b 0.20 -s 2 -n 5000 -w > outL20b0.20
./is -L 20 -b 0.30 -s 2 -n 5000 -w > outL20b0.30
./is -L 20 -b 0.40 -s 2 -n 5000 -w > outL20b0.40
./is -L 20 -b 0.42 -s 2 -n 5000 -w > outL20b0.42
./is -L 20 -b 0.44 -s 2 -n 5000 -w > outL20b0.44
./is -L 20 -b 0.46 -s 2 -n 5000 -w > outL20b0.46
./is -L 20 -b 0.48 -s 2 -n 5000 -w > outL20b0.48
./is -L 20 -b 0.50 -s 2 -n 5000 -w > outL20b0.50
./is -L 20 -b 0.60 -s 2 -n 5000 -w > outL20b0.60
./is -L 20 -b 0.70 -s 2 -n 5000 -w > outL20b0.70
```

The first line is a comment, since everything after a `#` is ignored by the shell. The second line starts a simulation from a hot configuration (-s 1), lattice size L=20 (-L 20) and temperature $\beta = 0.10$ (-b 0.10). The seed for the random number generator is set equal to 3423 (-S 3423) and we measure on 5000 Wolff clusters (-n 5000 -w). The results, printed to the stdout, are redirected to the file `outL20b0.10` (> outL20b0.10).

The next ten lines continue the simulation for $\beta = 0.20 - 0.70$. Each simulation starts from the configuration stored in the file `conf` at the end of the previous simulation.

In order to run these commands, the file `run1` should be given execute permissions (only once, the permissions ... stay after that) using the command `chmod`:

```
> chmod a+x run1
```

Then `run1` can be executed like any other command:

```
> ./run1
```

Not bad... But we can do better! Instead of adding one line for each simulation, we can use the programming capabilities of the shell. Let’s see how. The file `run2` contains the commands:

```
#!/bin/tcsh -f
```
The first line calls the shell tcsh in order to interpret the script. This was not necessary in run1, since every shell can interpret the commands that it contains. But in this case we use syntax which is special to the shell tcsh.

The second line is a comment.

The third line defines a shell variable whose name is L. Its value is set after the = character equal to the string "20". This value is accessible by adding a $ in front of the name of the variable. Therefore, whenever we write $L (or ${L}), the shell substitutes the string of characters 20. For example, in place of outL${L}b the shell constructs the string outL20b.

The fourth line defines an array, whose name is betas. The different elements of the array can be accessed by using the syntax $betas[number], where “number” is the array element starting from 1. In the example shown above $betas[1]= 0.10, $betas[2]= 0.20, ..., $betas[11]= 0.70. The special variable $#betas is the number of elements in the array, which is equal to 11. When we write $betas, the shell expands it to all the values in the array.

The fifth line defines the variable start to be equal to the string of characters "-s 1 -S 3423". The quotes have been put because we want it to be treated as a single string of characters. If we omit them, then the shell treats -s, 1, -S and 3423 as separate words, and we obtain a syntax error. Everything after the character # is a comment.

The command foreach is a way to construct a loop in tcsh. The commands between the foreach and end repeat once for every word in the parentheses in the foreach line. Each time, the loop variable, whose name is put after the keyword foreach, is set equal to the next word.

---

¹⁹The syntax is very strict and the line has to start exactly with the characters #! The string following #! can be the name of any program in the filesystem, which will be used to interpret the script.

²⁰Try the command: echo $betas[3] $#betas $betas
### 14.5. Data Analysis

Data production must be monitored by looking at the time histories of properly chosen observables. This will allow us to spot gross mistakes and it will serve as a qualitative check of whether the system has thermalized and how long are the autocorrelation times. It is easy to construct

```plaintext
#!/bin/tcsh -f

set Ls = (10 20 40)
set betas = (0.10 0.20 0.30 0.40 0.42 0.44 0.46 0.48 0.50
            0.60 0.70)
set nsweeps = 5000

foreach L ($Ls)
    set start = "-s 1 -S 3423"

foreach beta ($betas)
    echo "L= $L beta= $beta"
    ./is -L $L -b $beta -n $nsweeps -w $start > outL$Lb$beta
    set start = "-s 2"
end
end
```

The array variable Ls stores as many L as we wish. Note that the definitions of start are put in a special place (why?).

Data production must be monitored by looking at the time histories of properly chosen observables. This will allow us to spot gross mistakes and it will serve as a qualitative check of whether the system has thermalized and how long are the autocorrelation times. It is easy to construct...
time histories using gnuplot. For example, the commands

```bash
gnuplot> plot "<grep -v "#' outL40b0.44" \ 
    u 1 with lines title "E"
```  
```bash
gnuplot> plot "<grep -v "#' outL40b0.44" \ 
    u (abs($2)) with lines title "|M|
```  
```bash
gnuplot> plot "<awk '/#clu/{print $2}' outL40b0.44" \ 
    u 1 with lines title "n"
```
show us the time histories of the energy, of the (absolute value of the) magnetization and of the size of the clusters in a simulation with $L = 40$ and $\beta = 0.44$.

The expectation values of the energy per link $\langle e \rangle = \frac{1}{2N} \langle E \rangle$ and the magnetization per site $\langle m \rangle = \frac{1}{L} \langle M \rangle$ with their errors can be calculated by the jackknife program, which can be found in the file jack.f90 in the directory Tools (see appendix 13.8). We compile the program into an executable file jack which we copy into the current working directory. The expectation value $\langle e \rangle$ can be calculated using the command:

```bash
> grep -v # outL40b0.44 | \ 
awk -v L=40 'NR>500{print $1/(2*L*L)}' | ./jack
```

We pass the value L=40 to the program awk by using the option -v, therefore making possible the calculation of the ratio of the first column $\langle e \rangle$ by $2N = 2L^2$. The condition NR>500 makes the printing command to be executed only after awk reads the first 500 lines²². This way we can discard a number of thermalization sweeps. The result of the above command is printed to the stdout as follows:

```
# NDAT = 4500 data. JACK = 10 groups  
# <\langle e \rangle>, chi= (<\langle e \rangle^2>−<\langle e \rangle^2)  
# <\langle e \rangle> +/- err chi +/- err  
−0.7109116666 0.0024162628283 0.0015719190590 7.819205433e−05
```

The first three lines are the comments printed by the program jack, which inform the user about the important parameters of the analysis. The last line gives $\langle e \rangle$ and its error and then the fluctuations $\langle e^2 \rangle − <\langle e \rangle^2$ and their error. The latter must be multiplied by $\beta^2 N$, in order to obtain the specific heat $c$ and its error according to (13.29). By adding a few

²¹The plot command accepts, in place of the name of a data file, the stdout of a command command using the syntax plot "<command>".

²²NR is the number of lines (number of records) read by awk so far.
more lines to the command shown above, this multiplication can be done on the fly:

```
> set L = 40; set b = 0.44 ;
grep -v # out$L{L}$b${b}
awk -v L=$L 'NR>500{ print $1/(2*L*L)}'
./jack | grep v#
awk -v L=$L -v b=$b
 '{ print "e",L,b,$1,$2,b*L*L*3,b*L*L*4}'}
```

Well, why all this fuzz? Notice that all the commands shown above can be given in one single line in the command line (by removing the trailing \
of each line). By recalling the command, it is easy to obtain the results for a different value of $L$ and/or $\beta$, by editing the values of the variables $L$ and/or $b$. The result is

```
e 40 0.42 -0.619523333 0.00189807 0.311391 0.0228302
```
i.e. $\langle e \rangle = -0.6195(19)$ and $c = 0.311(23)$.

We can work in a similar way for computing the magnetization. We have to calculate the absolute value of the second column of the stdout of the command ./is, for every line that does not start with a #:

```
> set L = 40 ; set b = 0.42 ;
grep -v # out$L{L}$b${b}
awk -v L=$L 'NR>500{ m=($2>0)?$2:-$2; print m/(L*L)}'
./jack | grep v#
awk -v L=$L -v b=$b
 '{ print "m",L,b,$1,$2,b*L*L*3,b*L*L*4}'}
```
The absolute value is calculated by the expression $(\$2>0)?$2:-$2$, and it is stored in the variable $m$, which in turn is printed after being divided by $N = L^2$. The result is

```
m 40 0.44 0.6250527778 0.00900370 21.8345 1.39975
```
which gives $\langle m \rangle = 0.6251(90)$ and $\chi = 21.8(14)$.

Similarly we can calculate $\langle n \rangle / N$:

```
> set L = 40 ; set b = 0.44 ;
grep '#clu' out$L{L}$b${b}
awk -v L=$L 'NR>500{ print $2/(L*L)}'
```

```
```
The result is

\[ n = 40 \quad 0.44 \quad 0.4257476389 \quad 0.01302602 \]

which gives \( \langle n \rangle / N = 0.426(13) \).

All of the above commands can be summarized in the script in the file run3:

```bash
#!/bin/tcsh

set Ls = (10 20 40 60 80 100)
set betas = (0.00 0.10 0.20 0.25 0.30 0.34 0.38 \0.40 0.42 0.43 0.44 0.45 0.46 0.48 \0.48 0.50 0.55 0.60 0.65 0.70 0.80 )
set nsweeps = 100000
```
14.5. DATA ANALYSIS

Figure 14.7: The results of the simulations performed by the shell script in the file run3. The magnetic susceptibility $\chi$ is shown to be almost independent of the lattice size when $\beta$ takes values away from the critical region. In the critical region, its value increases as shown in equation (13.10).

```bash
foreach L ($Ls )
set start = "-s 1 -S 3423"
foreach beta ($betas)
  ./is -L $L -b $beta -n $nsweeps -w $start > outL$b{beta}
  set start = "-s 2"
  # Calculate $\langle e \rangle = \langle E \rangle / (2N)$ and $c=beta^2 N^2 \langle e^2 \rangle - \langle e \rangle^2$:
  grep -v '#' outL$b{beta} | \
  awk -v L=$L 'NR>500{ print $1/(2*L*L)' | \
  ./jack | grep -v '#'
  awk -v L=$L -v b=$beta \
    '{ print e".L.b.$1.$2.b*b*L*L*$3.b*b*L*L*$4}'}
    # Calculate $\langle m \rangle = \langle |M| \rangle / N$ and $ch=beta*N^2 \langle m^2 \rangle - \langle m \rangle^2$:
  grep -v '#' outL$b{beta} | \
  awk -v L=$L 'NR>500{m=($2>0)?$2:-$2; print m/(L*L)'} | \
  ./jack | grep -v '#'
  awk -v L=$L -v b=$beta \
    '{ print "m".L.b.$1.$2.b*L*L*$3.b*L*L*$4}'}
end
end
```
The script is run with the command

```
> ./run3 > out &
```

Then, we can plot the results using gnuplot:\footnote{These are gnuplot commands, even though we do not follow the usual convention to show the prompt `gnuplot>` explicitly}

```plaintext
set xlabel "beta"
set ylabel "<\(\phi\)"
plot "<grep '^[m 10 ' out" u 3:4:5 with errorbars title " 10"
replot "<grep '^[m 20 ' out" u 3:4:5 with errorbars title " 20"
replot "<grep '^[m 40 ' out" u 3:4:5 with errorbars title " 40"
replot "<grep '^[m 60 ' out" u 3:4:5 with errorbars title " 60"
replot "<grep '^[m 80 ' out" u 3:4:5 with errorbars title " 80"
replot "<grep '^[m 100 ' out" u 3:4:5 with errorbars title "100"
```

The above commands plot the magnetization.

Figure 14.8: The results of the simulations performed by the shell script in the file run3. The plot shows the expectation value \(<\(e\)>\).
Figure 14.9: The results of the simulations performed by the shell script in the file run3. The plot shows the specific heat $c$ which is shown to be almost independent of $L$ away from the critical region, whereas in the critical region it increases according to equation (13.8).

The above commands plot the magnetic susceptibility.

```bash
set ylabel "\chi"
set log y
plot "<grep '^m 10 ' out" u 3:6:7 with errorbars title "10"
replot "<grep '^m 20 ' out" u 3:6:7 with errorbars title "20"
replot "<grep '^m 40 ' out" u 3:6:7 with errorbars title "40"
replot "<grep '^m 60 ' out" u 3:6:7 with errorbars title "60"
replot "<grep '^m 80 ' out" u 3:6:7 with errorbars title "80"
replot "<grep '^m 100 ' out" u 3:6:7 with errorbars title "100"
```

```bash
set ylabel "\langle e \rangle"
plot "<grep '^e 10 ' out" u 3:4:5 with errorbars title "10"
replot "<grep '^e 20 ' out" u 3:4:5 with errorbars title "20"
replot "<grep '^e 40 ' out" u 3:4:5 with errorbars title "40"
replot "<grep '^e 60 ' out" u 3:4:5 with errorbars title "60"
replot "<grep '^e 80 ' out" u 3:4:5 with errorbars title "80"
replot "<grep '^e 100 ' out" u 3:4:5 with errorbars title "100"
```
Figure 14.10: The results of the simulations performed by the shell script in the file run3. The plot shows $\langle n \rangle / N$.

The above commands plot the energy.

```
set ylabel "c"
plot "<grep '^[e 10 ' out" u 3:6:7 with errorbars title "10"
replot "<grep '^[e 20 ' out" u 3:6:7 with errorbars title "20"
replot "<grep '^[e 40 ' out" u 3:6:7 with errorbars title "40"
replot "<grep '^[e 60 ' out" u 3:6:7 with errorbars title "60"
replot "<grep '^[e 80 ' out" u 3:6:7 with errorbars title "80"
replot "<grep '^[e 100 ' out" u 3:6:7 with errorbars title "100"
```

The above commands plot the specific heat.

```
set ylabel "<$n$>/N"
plot "<grep '^[n 10 ' out" u 3:4:5 with errorbars title "10"
replot "<grep '^[n 20 ' out" u 3:4:5 with errorbars title "20"
replot "<grep '^[n 40 ' out" u 3:4:5 with errorbars title "40"
replot "<grep '^[n 60 ' out" u 3:4:5 with errorbars title "60"
replot "<grep '^[n 80 ' out" u 3:4:5 with errorbars title "80"
```
14.6. Autocorrelation Times

The above commands plot $\langle n \rangle / N$.

14.6 Autocorrelation Times

In the case of the Metropolis algorithm, the “unit of time” in the Monte Carlo simulation is one “sweep”, which is equal to $N$ attempted spin flips. In the case of the Wolff algorithm, the size of the clusters is a stochastic variable, which depends on temperature. Therefore, flipping the spins of a cluster is not a convenient unit of time, and we define:

$$(1 \text{ sweep}) = \frac{N}{\langle n \rangle} \text{(Wolff cluster updates)} \quad (14.30)$$

This definition of a sweep can be compared to a Metropolis sweep defined as $N$ accepted spin flips\[24. For convenience, we also use the $\beta$–dependent unit of time equal to one Wolff cluster update. We use the notation $\tau^W_\mathcal{O}$ when the autocorrelation time of $\mathcal{O}$ is measured in Wolf cluster updates, and $\tau_\mathcal{O}$ when using the definition (14.30). Their relation is:

$$\tau_\mathcal{O} = \tau^W_\mathcal{O} \frac{\langle n \rangle}{N}. \quad (14.31)$$

We simulate the Ising model for $L = 10, 20, 40, 60, 80$ and 100 at $\beta = 0.4407$ using the Wolff algorithm. We construct $5 \times 10^6$ Wolff clusters. The results are written to files with names out$L$b0.4407. We also perform simulations using the Metropolis algorithm with $10 \times 10^6$ sweeps. The results are written to files with names out$L$b0.4407met. The following shell script makes life easier:

```
#!/bin/tcsh -f
set Ls = (10 20 40 60 80 100)
set beta = 0.4407
set nsweeps = 5000000
set start = "-s 1 -S 3423"
# Wolf cluster algorithm:
foreach L ($Ls)
./is -w -L $L -b $beta -n $nsweeps $start > out$L$b$beta
# Mean cluster size $\langle n \rangle / N$
```

The two definitions of a sweep in the Metropolis algorithm differ by a factor equal to the average acceptance rate. Both definitions are used in the bibliography, and the reader (as well as the author) of a scientific article should be aware of that.
CHAPTER 14. CRITICAL EXPOUNTS

We compile the file autoc.f90 from the Tools directory and the executable file is named autoc and copied to the current working directory. Then, the following shell script calculates the autocorrelation functions \( \rho_m(t) \):

```bash
#!/bin/tcsh -f
set Ls = (10 20 40 60 80 100)
set b = 0.4407
# Wolff
set tmax = 1000
set ndata = 5000000
foreach L ($Ls)
  set f = outL$L/b/met
  grep -v '#' $f |
  awk -v L=$L -v b=$beta '{
    print n,L,b,$1,$2}'
  autoc t $tmax -n $ndata > $f.rhom
end

# Metropolis
set tmax = 8000
set ndata = 10000000
foreach L ($Ls)
  set f = outL$L/b/met
  grep -v '#' $f |
  awk -v L=$L -v b=$beta '{
    print n,L,b,$1,$2}'
  autoc t $tmax -n $ndata > $f.rhom
end
```

We throw away 100 000 sweeps for thermalization. The results are written to files whose names have file extension .rhom. The function \( \rho_m(t) \) is fitted to \((13.51)\) using three autocorrelation times according to the discussion in appendix \( \text{[13.7]} \). The results are shown in table \( \text{[14.1]} \).

\( ^{35} \)Notice the difference between the results of the Metropolis algorithm and the ones shown in appendix \( \text{[13.7]} \). The difference is due to a fivefold increase in the statistics and
14.6. AUTOCORRELATION TIMES

\[ \langle n \rangle / N \]

The autocorrelation time for the magnetization calculated as described in the text. The second column contains the autocorrelation time \( \tau_m^W \) for the Wolff algorithm, using one cluster update as the unit of time. The fourth column contains \( \tau_m \) in sweeps according to (14.30) and we have that \( \tau_m = \tau_m^W \langle n \rangle / N \) (see (14.31)). The fifth column contains the autocorrelation times for the Metropolis algorithm in units of sweeps defined as \( N \) attempted spin flips.

From (14.10) we expect that \( \tau_m \sim L^z \) where \( z \) is the dynamic exponent. \( z \) can be calculated by the gnuplot commands:

```plaintext
gnuplot> tau(x) = c*x**z

gnuplot> fit tau(x) "autoc.dat" u 1:2:3 via c,z

gnuplot> plot "autoc.dat" u 1:2:3 w e t "W steps ", tau(x)

gnuplot> fit tau(x) "autoc.dat" u 1:6:7 via c,z

gnuplot> plot "autoc.dat" u 1:6:7 w e t "W sweeps ", tau(x)

gnuplot> fit tau(x) "autoc.dat" u 1:8:9 via c,z

gnuplot> plot "autoc.dat" u 1:8:9 w e t "Metropolis", tau(x)
```

The exponent \( z \) is calculated for the Wolff algorithm in Wolff steps and Wolff sweeps. The results are:

\[ \tau_m^W \sim L^z^W, \quad z^W = 0.54 \pm 0.02 \]  
(14.32)

\[ \tau_m \sim L^z, \quad z = 0.29 \pm 0.02 \]  
(14.33)

\[ \tau_{m, \text{Metropolis}} \sim L^z, \quad z = 2.21 \pm 0.02 \]  
(14.34)

The plots are shown in figures 14.11-14.13. The values of \( z \) reported in the bibliography are 0.50(1), 0.25(1) and 2.167(1) respectively [4,50,67]. We can obtain better results by increasing the statistics and the lattice size and this is left as an exercise for the reader.

shows that the real error in the calculation of \( \tau \) includes systematic errors that have been neglected.
Figure 14.11: Autocorrelation times $\tau^W_m$ for the magnetization using the Wolff algorithm at $\beta = 0.4407$. The unit of time is one Wolff cluster update. The dynamic exponent is calculated from the fit to $cL^{z_W}$ which gives $z^W = 0.54(2)$.

We also mention the relation between the dynamic exponents given by equations (14.32) and (14.33). From (14.29) $\chi = \beta \langle n \rangle$, (13.10) $\chi \sim |t|^{-\gamma}$, and (13.3) $\xi \sim |t|^{-\nu}$ and using $\xi \sim L$, valid in the critical region, we obtain

$$\tau_m = \frac{\tau^W_m \langle n \rangle}{L^2} \sim L^{z_W} L^{\gamma/\nu} L^2 = L^{z_W + \gamma/\nu - 2},$$

where we assumed that $\tau^W_m \sim L^{z_W}$, $z^W \equiv 0.54(2)$ and $\tau_m \sim L^z$. Therefore

$$z = z^W + \frac{\gamma}{\nu} - 2.$$ 

(14.36)

Using the values given in (13.12), $\gamma = 7/4$, $\nu = 1$, we obtain

$$z = z^W - \frac{1}{4},$$ 

(14.37)

which is in agreement, within error, with the calculated values and the values in the bibliography.
14.6. AUTOCORRELATION TIMES

Table 14.4: The critical exponents $\gamma/\nu$ and $\beta/\nu$ given by the finite size scaling relations (14.7) and (14.9). The first column contains the range in $L$ included in the fits of $\chi(\beta_c, L)$ and $\langle m \rangle (\beta_c, L)$ to $aL^\eta$. 
14.7 Temperature Scaling

In this section we will discuss the extent to which relations (14.3)–(14.5) can be used for the calculation of the critical exponents $\gamma, \alpha$ and $\beta$. The result is that, although using them it is possible to compute correct results, these relations are not the best choice.\footnote{Note that for the Ising model on the square lattice, the critical temperature is exactly known. In a model where it is not known we have larger systematic errors than the ones discussed here. The numerical calculation of the critical temperature we will discussed in a following section.} In order to see clear scaling and reduce finite size effects, we have to consider $t \ll 1$ and large $L$. The results depend strongly on the choice of range of the data included in the fits. The systematic errors are large and the results in some cases plain wrong.\footnote{In \cite{4} it is mentioned that the random field Ising model exhibits pseudoscaling for a range of $t$ and for even smaller $t$ there is a crossover to a different scaling that gives the correct critical exponent. See also \cite{68}, \cite{69}.}

We simulate the Ising model for $L = 40, 60, 80, 100, 120, 140, 160, 200$ and $500$. The temperatures chosen correspond to small enough $t$ in order to observe scaling. For the values of $\beta$ used in the simulations, see

---

Figure 14.12: Autocorrelation times $\tau_m$ for the magnetization using the Wolff algorithm at $\beta = 0.4407$. The unit of time is one Wolff sweep. The dynamic exponent is calculated from the fit to $cL^z$, which gives $z = 0.29(2)$. 
the shell scripts in the accompanying software.

First we compute the exponent $\gamma$ from the relation (14.3). For given $L$, we fit the data for $\chi(t)$ for an appropriate range of $|t|$ to the function $a |t|^{-\gamma}$, which has two fitting parameters, $\gamma$ and $a$. We determine the range of $t$ where $\chi(t)$ gives a linear plot in a log–log scale. For large $|t|$, we observe deviations from the linear behavior and for very small $|t|$ we observe finite size effects when $\xi \approx L$. As $L$ increases, finite size effects decrease, and the data get closer to the asymptotic behavior $|t|^{-\gamma}$ for even smaller $|t|$. The results are more clear for $\beta > \beta_c(t < 0)$, because for $t > 0$ the fluctuations near the pseudocritical temperature $\beta_c(L) < \beta_c$ are larger and the finite size effects are larger.

Table 14.2 shows the results for the exponent $\gamma$ for all the measured values of $L$. The errors reported are the statistical errors of the fits, which are smaller than the systematic errors coming from the choice or range of $t$ of the data included in the fits. One has to vary this range as long as the $\chi^2$/dof of the fit remains acceptable, and the resulting variation in the values of the parameters has to be included in the estimate of the

\footnote{The fit can also be done by linearly fitting the points $(\log |t_i|, \log \chi(t_i))$ to a straight line.}
CHAPTER 14. CRITICAL EXPO NENTS

Figure 14.14: The magnetic susceptibility $\chi(t, L)$ in the scaling region according to equation (14.3). The straight line is the fit to this relation for the largest lattice. We observe that finite size effects decrease as $L$ increases and that the range of temperatures included in the fit extends to smaller $|t|$. The data is for $\beta > \beta_c (t < 0)$ and the critical point is approached from the ordered phase.

error. Sometimes, this method gives an overestimated error, and it is a matter of experience to decide which parameter values to include in the estimate. For example, figures 14.14 and 14.15 show that the acceptable range of fitting becomes more clear by studying $\chi(t)$ for increasing $L$. As $L$ increases, the points approach the asymptotic curve even closer. Even though for fixed $L$ one obtains acceptable power fits over a larger range of $t$, by studying the large $L$ convergence, we can determine the scaling region with higher accuracy. Another point to consider is whether the parameters of the fits have reasonable values. For example, even though the value of $a$ is unknown, it is reasonable to expect that its value is of order $\sim 1$. By taking all these remarks into consideration we obtain

$$\gamma = 1.74 \pm 0.02 \quad (t < 0), \quad (14.38)$$

$$\gamma = 1.73 \pm 0.04 \quad (t > 0). \quad (14.39)$$

Next, we compute the critical exponent $\beta$ using relation (14.5). This relation is valid as we approach the critical point from the low temperature phase, $\beta > \beta_c$ or $t < 0$. In the thermodynamic limit, the magnetization
14.7. TEMPERATURE SCALING

Figure 14.15: The magnetic susceptibility $\chi(t, L)$ in the scaling region according to equation (14.3). The straight line is the fit to this relation for the largest lattice. We observe that finite size effects decrease as $L$ increases and that the range of temperatures included in the fit extends to smaller $|t|$. The data is for $\beta < \beta_c(t > 0)$ and the critical point is approached from the disordered phase. Finite size effects are larger for $t < 0$ due to the larger fluctuations at the pseudocritical point $\beta_c(L) < \beta_c$.

is everywhere zero for all $\beta < \beta_c$. For a finite lattice $\langle m \rangle > 0$, and it is reasonable to expect a scaling of the form

$$\langle m \rangle \sim |t|^{\beta_-^{-1}}, \quad t > 0,$$  \hspace{1cm} (14.40)

where $\beta_+$ is defined so that

$$\beta_+ = \beta = 1/8.$$  \hspace{1cm} (14.41)

By following the same procedure, we calculate the exponents $\beta$ and $\beta_+$ shown in table 14.3. By taking the systematic errors described above into consideration, we find that

$$\beta = 0.121 \pm 0.003 \quad t < 0,$$  \hspace{1cm} (14.42)

$$\beta_+ = 0.120 \pm 0.007 \quad t < 0,$$  \hspace{1cm} (14.43)

which should be compared to the expected values $\beta = \beta_+ = 1/8$. 
The calculation of the exponent \( \alpha \) needs special care. The expected value is \( \alpha = 0 \). This does not imply that \( \beta \) const. but that
\[
c \sim |\log |t|| .
\]
In this case, we find that the data is better fitted to the above relation instead of being fitted to a power. This can be seen pictorially by making a log–log plot and comparing it to a \( c - |\log |t|| \) plot. We see that the second choice leads to a better linear plot than the first one. A careful study will compute the quality of the fits and choose the better model this way. This is left as an exercise for the reader.

## 14.8 Finite Size Scaling

In this section we will calculate the critical exponents by using relations (14.7)–(14.9), i.e., by using the asymptotic scaling of \( \chi(\beta = \beta_c, L) \), \( c(\beta =
Figure 14.17: The magnetization $\langle m \rangle(t, L)$ in the scaling region fitted to equation (14.40). The straight line is the fit to this relation for the largest lattice. We observe that finite size effects decrease as $L$ increases and that the range of temperatures included in the fit extends to smaller $|t|$. The data is for $\beta < \beta_c(t > 0)$ and the critical point is approached from the disordered phase.

$\beta_c, L)$ and $\langle m \rangle(\beta = \beta_c, L)$ with increasing system size $L$. This is called “finite size scaling”.

In order to calculate the exponent $\gamma/\nu$ given by equation (14.7), we calculate the magnetic susceptibility at the known $\beta_c$ for increasing values of $L$. We fit the results $\chi(\beta_c, L)$ to the function $a L^g$ and calculate the fitting parameters $a$ and $g$. Then, we compare the computed value of $g$ to the expected value of $\gamma/\nu = 7/4 = 1.75$. In this procedure we have to decide which values of $L$ should be included in the fits. The most obvious criterion is to obtain reasonable $\chi^2/\text{dof} \leq 1$ and that the error in $g$ and $a$ be small. This is not enough: Table 14.4 shows small variations in the obtained values of $\gamma/\nu$, if we consider different fit ranges. These variations give an estimate of the systematic error which enters in the calculation. Problem 9 is about trying this calculation yourselves. Table 14.4 shows the results, and figure 14.20 shows the corresponding plot. The final result, which includes also an estimate of the systematic errors, is

$$\frac{\gamma}{\nu} = 1.748 \pm 0.005.$$  

(14.45)

For the calculation of the exponent $\beta/\nu$ given by equation (14.9), we compute the magnetization $\langle m \rangle(\beta_c, L)$ at the critical temperature and
repeat the same analysis. The result is

$$\frac{\beta}{\nu} = 0.1245 \pm 0.0006. \quad (14.46)$$

Equation (14.9) gives the exponent $\alpha/\nu$. But the expected value $\alpha = 0$ leads, in analogy with equation (14.44), to

$$c(\beta_c, L) \sim \log L. \quad (14.47)$$

This relation is shown in figure 14.22. The vertical axis is not in a logarithmic scale whereas the horizontal is. The linear plot of the data shows consistency with equation (14.47). Problem 9 asks you to show whether the logarithmic fit is better than a fit to a function of the form $cL^\alpha + b$ and appreciate the difficulties that arise in this study. By increasing the statistics, and by measuring for larger $L$, the data in table 14.8 will improve and lead to even clearer conclusions.

We observe that, by using finite size scaling, we can compute the critical exponents more effectively, than by using temperature scaling as in section 14.7. The data follow the scaling relations (14.7)–(14.9) suffering smaller finite size effects\[30\].

\[30\]Remember that the instability of the results with respect to the choice of the fitting range is large for the temperature scaling method. When the exact value of the critical temperature is not known, the superiority of finite size scaling is even higher.
In the previous sections we discussed scaling in $t$ and $L$ in the critical region. In the calculations we used the exact value of the critical temperature $\beta_c = \log(1 + \sqrt{2})/2$. When $\beta_c$ is not known, the analysis becomes harder and its computation contributes to the total error in the value of the critical exponents. When doing finite size scaling using the scaling relations (14.7)–(14.9), one has to choose the values of the temperature at which to calculate the left hand sides. So far, these values were computed at $\beta_c$. What should we do when $\beta_c$ is not a priori known? A good choice is to use the pseudocritical temperature $\beta_c(L)$, the temperature where the fluctuations of the order parameter $\chi(\beta)$ are at their maximum. Otherwise, we can compute $\beta_c$ according to the discussion in this section and use the computed $\beta_c$ in the finite size scaling analysis.

Both choices yield the same results in the large $L$ limit, even though the finite size effects are different. In fact any value of $\beta$ in the critical region can be used for this calculation. The reason is that as we approach the critical region for given $L$, the correlation length becomes $\xi \sim L$ and finite size effects become important. This is the behavior that characterizes the pseudocritical region of the finite $L$ system. The pseudocritical region becomes narrower as $L$ becomes larger. Any value of $\beta$ in this region

Figure 14.19: The specific heat $c(t, L)$ in the scaling region fitted to equation (14.44). Only the $|t|$ axis is in logarithmic scale. The data is for $\beta < \beta_c (t > 0)$ and the critical point is approached from the disordered phase. The exponent $\nu$ is set equal to 1.
will give us observables that scale at large $L$, but the best choice is

$$\chi(\beta_c(L), L) \equiv \chi_{\text{max}}(L). \quad (14.48)$$

In this case, the values on the left hand sides of (14.7)–(14.9) should be taken at $\beta = \beta_c(L)$.

The definition of $\beta_c(L)$ in not unique. One could use, for example, the maximum of the specific heat

$$c(\beta'_c(L), L) \equiv c_{\text{max}}(L), \quad (14.49)$$

which defines a different $\beta'_c(L)$. Of course $\lim_{L \to \infty} \beta_c(L) = \lim_{L \to \infty} \beta'_c(L) = \beta_c$ and both choices will yield the same results for large $L$. The speed of convergence and the errors involved in the calculation of the pseudocritical temperatures are different in each case and there is a preferred choice, which in our case is $\beta_c(L)$.

First we calculate $\beta_c$. When we are in the pseudocritical region we have that $\xi \approx L$, therefore (14.2) gives

$$|t| = \left| \frac{\beta_c - \beta_c(L)}{\beta_c} \right| \sim \xi^{-\frac{1}{\nu}} \sim L^{-\frac{1}{\nu}} \Rightarrow \beta_c(L) = \beta_c - \frac{c}{L^\sigma}. \quad (14.50)$$
14.9. CALCULATION OF $\beta_C$

The calculation is straightforward to do: First we measure the magnetic susceptibility. For each $L$ we determine the pseudocritical region and we calculate $\beta_c(L)$ and the corresponding maximum value $\chi_{\text{max}}$. In order to do that, we should take many measurements around $\beta_c(L)$. We have to be very careful in determining the autocorrelation time (which increases as $\tau \sim L^z$), so that we can control the number of independent measurements and the thermalization of the system. We use the relation (14.50) and fit the results to $a - c/L^b$, and from the calculated parameters $a$, $b$ and $c$ we compute $\beta_c = a$, $\nu = 1/b$. In cases where one of the parameters $\beta_c$, $\nu$ is known independently, then it is kept constant during the fit.

The results are shown in figure 14.23 where we plot the numbers contained in table 14.5. The final result is:

$$\beta_c = 0.44066 \pm 0.00003$$

$$\frac{1}{\nu} = 1.006 \pm 0.017.$$ 

This can be compared to the known values $\beta_c = \log(1 + \sqrt{2})/2 \approx 0.44069$ and $1/\nu = 1$.

This process is repeated for the pseudocritical temperatures $\beta'_c(L)$ and the maximum values of the specific heat $c_{\text{max}}$. The results are shown in

---

**Figure 14.21**: The magnetization $\langle m \rangle(\beta_c, L)$ at the critical temperature for different values of $L$. The axes are in a logarithmic scale and the linear plots are consistent with the power fit $\langle m \rangle(\beta_c, L) = cL^g$. The value of $g$ computed by the fits is consistent with the critical exponent $\beta/\nu$ given by equation (14.3).
Figure 14.22: The specific heat $c(\beta_c, L)$ at the critical temperature for different values of $L$. The horizontal axis is in a logarithmic scale and the linear plot is consistent with the scaling relation $c(\beta_c, L) = c \log L$. The result is consistent with the expectation $\alpha = 0$ (see equation (14.8)).

Figure 14.24. The final result is:

$$\beta_c = 0.44062 \pm 0.00008$$
$$\frac{1}{\nu} = 1.09 \pm 0.18.$$

Figure 14.24 and the results reported above show that the calculation using the specific heat gives results compatible with (14.51), but that they are less accurate. The values of the specific heat around its maximum are more spread and more noisy than the ones of the magnetic susceptibility.

From the maxima of the magnetic susceptibility $\chi_{\text{max}}(L)$ we can calculate the exponent $\gamma/\nu$. Their values are shown in table 14.5. The data are fitted to $aL^b$, according to the asymptotic relation (14.3), with $a$ and $b$ being fitting parameters. We find very good scaling, therefore our data are in the asymptotic region. The result is

$$\frac{\gamma}{\nu} = 1.749 \pm 0.001,$$

which is consistent with the analytically computed value $7/4$.

From the maxima of the specific heat we can calculate the exponent $\alpha/\nu$. Since $\alpha = 0$, the form of the asymptotic behavior is given by (14.47).

Table 14.5: The pseudocritical temperatures $\beta_c(L)$ and $\beta'_c(L)$ calculated from the maxima of the magnetic susceptibilities $\chi_{\text{max}}$ and the specific heat $c_{\text{max}}$ respectively. The values of the maxima are also shown.

We find that our results are not very well fitted to the function $a \log L$ and it is possible that the discrepancy is due to finite size effects. We add terms that are subleading in $L$ and find that the fit to the function $a \log L + b - c/L$ is very good. If we attempt to fit the data to the function $a L^d + b - c/L$, the quality of the fit is poor and the result for $d$ is consistent with zero. The results are shown in figure 14.26.

14.10 Studying Scaling with Collapse

The scaling relations (14.3)–(14.9) are due to the appearance of a unique, dynamical length scale, the correlation length $\xi$. As we approach the critical point, $\xi$ diverges as $\xi \sim |t|^{-\nu}$. and we obtain universal behavior for all systems in the same universality class. If we consider the magnetic susceptibility $\chi(\beta, L)$, its values depend both on the temperature $\beta$, the size of the system $L$ and of course on the details of the system’s degrees of freedom and their dynamics. Universality leads to the assumption that the magnetic susceptibility of the infinite system in the critical region depends only on the correlation length $\xi$. For the finite system in the pseudocritical region, finite size effects suppress the fluctuations when

---

³¹Our ansatz is justified by the analytic calculations in [70], which compute the corrections to the log $L$ behavior. These corrections are shown to be given by integer powers of $1/L$: $c = a \log L + \sum_{k=0}^{\infty} c_k/L^k$.

³²Careful: $\xi = \xi(t)$ is the correlation length of the infinite system at temperature $t$ and not the correlation length at finite $L$. 
CHAPTER 14. CRITICAL EXPONENTS

Figure 14.23: Calculation of the critical temperature $\beta_c$ and the critical exponent $\nu$ using relation (14.50). By using the pseudocritical temperatures $\beta_\text{c}(L)$ of table 14.5, we fit the data to $a - c(1/L)^\nu$. From the calculated values of $a$, $b$ and $c$ we calculate $\beta_c = a$ and $1/\nu = b$. The horizontal line is the exact, known value $\beta_c = \log(1 + \sqrt{2})/2 = 0.44069\ldots$

The length scales that determine the dominant scaling behavior $\chi \sim \xi^{\gamma/\nu}$ are $\xi$ and $L$, therefore the dimensionless variable $L/\xi$ is the only independent variable in the scaling functions. In order to obtain the scaling relation $\chi \sim \xi^{\gamma/\nu}$, valid for the infinite system, we only need to assume that for the finite system\(^{31}\)

$$\chi = \chi(\beta_c, L) = \xi^{\gamma/\nu} F_\chi^{(0)}(L/\xi),$$

(14.52)

where $F_\chi^{(0)}(z)$ is a function of one variable, such that

$$F_\chi^{(0)}(z) = \text{const.} \quad z \gg 1,$$

(14.53)

and

$$F_\chi^{(0)}(z) \sim z^{\gamma/\nu} \quad z \to 0.$$

(14.54)

Indeed, when $1 \ll \xi \ll L$ ($z \gg 1$) the magnetic susceptibility takes values very close to those of the infinite system, and (14.53) gives $\chi \sim \xi^{\gamma/\nu}$. As $\xi \sim L$, finite size effects enter and (14.54) gives $\chi \sim \xi^{\gamma/\nu}(L/\xi)^{\gamma/\nu} = L^{\gamma/\nu}$. The latter is nothing but (14.7) for the maxima of the magnetic susceptibility of the finite system that we studied in figure 14.25. Therefore the

\(^{31}\)For more details see appendix 14.12. The $\beta$ dependence in $\chi(\beta, L)$ enters through the dependence $\xi(\beta)$ of the correlation length of the infinite system in $\beta$. 
Figure 14.24: Calculation of the critical temperature $\beta_c$ and the critical exponent $\nu$ using relation (14.50). By using the pseudocritical temperatures $\beta'_c(L)$ of table 14.5, we fit the data to $a - c(1/L)^b$. From the calculated values of $a$, $b$ and $c$ we calculate $\beta_c = a$ and $1/\nu = b$. The horizontal line is the exact, known value $\beta_c = \log(1 + \sqrt{2})/2 = 0.44069\ldots$

The function $F^{(0)}_\chi(z)$ describes how the magnetic susceptibility deviates from scaling due to finite size effects.

The function $F^{(0)}_\chi(z)$ can be calculated using the measurements coming from the Monte Carlo simulation. Since the correlation length is not directly calculated, but appears indirectly in the measurements, we define the dimensionless variable

$$x = L^{1/\nu}t,$$  \hfill (14.55)

where $|x| \sim (L/\xi)^{1/\nu}$ since $\xi \sim |t|^{-\nu}$. We define $F^{(0)}_\chi(x) \propto x^{-\gamma}F^{(0)}_\chi(x')$ so that (14.52) becomes

$$\chi = L^{\nu/\nu}F^{(0)}_\chi(x) = L^{\nu/\nu}F^{(0)}_\chi(L^{1/\nu}t).$$  \hfill (14.56)

The asymptotic properties of the scaling function $F^{(0)}_\chi(x)$ are determined by the relations (14.53) and (14.54). When $x = L^{1/\nu}t \gg 1$, equation (14.53) is valid for $F^{(0)}_\chi(x')$ and we obtain $F^{(0)}_\chi(x') = \text{const}$. From the definition $F^{(0)}_\chi(x) = x^{-\gamma}F^{(0)}_\chi(x')$ we obtain $F^{(0)}_\chi(x) \sim x^{-\gamma} = (L/\xi)^{-\gamma/\nu}$ and we confirm

\footnote{The absolute value is dropped in the definition of $x$ so that we have a convenient notation for temperatures above and below the critical temperature.}
CHAPTER 14. CRITICAL EXPOUNTS

Figure 14.25: Calculation of the critical exponent $\gamma/\nu$ from the maxima of the magnetic susceptibility using the asymptotic scaling (14.9). The values $\chi_{\text{max}}(L)$ are taken from table (14.5) and are fitted to a function of the form $aL^{\gamma/\nu}$. The result of the fit is $\gamma/\nu = 1.749(1)$.

the scaling property of the magnetic susceptibility in the thermodynamic limit $\chi \sim L^{\gamma/\nu} F_\chi(x) \sim L^{\gamma/\nu} (L/\xi)^{-\gamma/\nu} = \xi^{\gamma/\nu}$. Therefore

$$ F_\chi(x) \sim x^{-\gamma} \quad x \gg 1. \quad (14.57) $$

When $x \to 0$, (14.54) is valid and we have that $F_\chi^{(0)}(x^\nu) \sim (x^\nu)^{\gamma/\nu} = x^\gamma$. Then we obtain $F_\chi(x) \propto x^{-\gamma} F_\chi^{(0)}(x^\nu) \sim x^{-\gamma} x^\gamma = \text{const}$. Therefore, we confirm that, when finite size effects are dominant ($x \to 0$), we have that $\chi = L^{\gamma/\nu} F_\chi(x) \sim L^{\gamma/\nu}$. Therefore

$$ F_\chi(x) \sim \text{const.} \quad |x| \ll 1. \quad (14.58) $$

By inverting equation (14.56), we can calculate the scaling function from the measurements of the magnetic susceptibility

$$ F_\chi(L^{1/\nu} t) = L^{-\gamma/\nu} \chi(\beta, L), \quad (14.59) $$

where $\chi(\beta, L)$ are measurements for temperatures in the pseudocritical region for several values of $L$. When equation (14.59) is valid, then all the measurements fall onto the same curve $F_\chi(x)$ independently of the size $L$! Of course deviations due to finite size effects are expected, especially when $L$ is small. But, as we will see, convergence is quite fast.
14.10. STUDYING SCALING WITH COLLAPSE

Figure 14.26: Calculation of the critical exponent $\alpha/\nu$ from the maxima of the specific heat using the asymptotic scaling (14.8). The values $c_{\text{max}}(L)$ are taken from table (14.5) and are fitted to a function of the form $a \log L + b - c/L$. We obtain $a = 0.107(3)$, $b = 0.13(1)$ and $c = 1.2(3)$ with $\chi^2/\text{dof} = 0.9$ by fitting for $L = 40, \ldots, 500$. The fit to $aL^d + b - c/L$ gives $d = 0.004(97)$, i.e., an exponent consistent with 0 and somehow weird values for the parameters $a$ and $b$. We conclude that the data is consistent with $\alpha/\nu = 0$.

Using the above procedure, we can determine the critical temperature $\beta_c$, the exponent $\nu$ and the ratio $\gamma/\nu$ simultaneously! In order to check (14.59), we have to compute the variable $x = L^{1/\nu}t$, for which it is necessary to know $\beta_c$ ($t = (\beta_c - \beta)/\beta_c$) and the exponent $\nu$. For the calculation of $F$, it is necessary to know $\gamma/\nu$ that appears on the right hand side of (14.59). Relation (14.59) depends quite sensitively on the parameters $\beta_c$, $\nu$ and $\gamma/\nu$ and this way we obtain an accurate method for their calculation.

In order to do the calculation, we set initial values for the parameters $(\beta_c, \nu, \gamma/\nu)$. Using $L$, $\beta$, $\beta_c$ and $\nu$, we calculate the scaling variable $x = L^{1/\nu}t = L^{1/\nu}(\beta_c - \beta)/\beta_c$. Using $\chi(\beta, L)$ and $\gamma/\nu$, we calculate $F_x = \chi(\beta, L)/L^{\gamma/\nu}$ and plot the points $(x_i, F_x(x_i))$ near the critical region $t \approx 0$. Then we vary $(\beta_c, \nu, \gamma/\nu)$ until the curves for different $L$ collapse onto each other. The optimal collapse determines $(\beta_c, \nu, \gamma/\nu)$.

The collapse of the curves that are constructed from the points $(L^{1/\nu}(\beta_c - \beta)/\beta_c, L^{1/\nu} \chi(\beta_c, L))$ for different $L$ is the most efficient method for studying scaling in the critical region. Figure 14.27 shows the function $F_x(x)$ for the known values of the parameters $(\beta_c, \nu, \gamma/\nu) = (\ln(1 +$
Figure 14.27: Collapse of the plots $\chi(\beta, L)$ for several values of $L$ according to equation (14.59). The known values $\beta_c = \ln(1 + \sqrt{2})/2, \nu = 1$ and $\gamma/\nu = 7/4$ have been used.

Small variations of the parameters lead to a sharp change of the quality of the collapse. We can make a quick and dirty estimate of the accuracy of the method by varying one of the parameters, and look for a visible deviation from all data collapsing onto a single curve. The result is

$$
\beta_c = 0.44069 \pm 0.00001
$$

$$
\nu = 1.00 \pm 0.01
$$

$$
\gamma/\nu = 1.750 \pm 0.002
$$

Notice that, this crude estimate yields results whose accuracy is comparable to the previously calculated ones!

A similar procedure can be followed for other scaling observables, like the specific heat and the magnetization. Equations (14.8) and (14.9) generalize to

$$
\langle m \rangle(\beta, L) = L^{-\beta/\nu} F_m(L^{1/\nu} t),
$$

\[\text{(14.60)}\]
Figure 14.28: Collapse of the plots $\langle m \rangle(\beta, L)$ for several values of $L$ according to equation (14.60). The known values $\beta_c = \ln(1 + \sqrt{2})/2$, $\nu = 1$ and $\beta/\nu = 1/8$ have been used.

and

$$c(\beta, L) = L^{\alpha/\nu} F_c(L^{1/\nu} t) = \log(L) F_c(L^{1/\nu} t),$$

(14.61)

since $\alpha = 0$. The results are shown in figures 14.28 and 14.29 respectively.

Below, we list a gnuplot program in order to construct plots like the ones shown in figures 14.27–14.29. If we assume that the data are in a file named all in the following format:\n

CHAPTER 14. CRITICAL EXPONENTS

Figure 14.29: Collapse of the plots \( c(\beta, L) \) for several values of \( L \) according to equation (14.61). The known values \( \beta_c = \ln(1 + \sqrt{2})/2 \) and \( \nu = 1 \) have been used.

where the lines starting with the character \( m \) contain \( (L, \beta, \langle m \rangle, \delta \langle m \rangle, \chi, \delta \chi) \) whereas the ones starting with \( e \) contain \( (L, \beta, \langle e \rangle, \delta \langle e \rangle, c, \delta c) \). The program can be found in the file scale_gamma.gpl:

```plaintext
# Usage:
# Ls = "40 60 80 100 120 140 160 200 500 1000"
# bc = bcc; nu = 1; gnu = 1.75; load "scale_gamma.gpl"
# Ls: the values of L used in the collapse
# bc: the critical temperature used in the calculation of
# t=(beta_c-beta)/beta_c
# nu: the exponent used in the calculation of x=L^[1/nu] t
# gnu: the exponent used in the calculation of
# F_chi = L^[-gnu] chi(beta,L)
# the exact critical temperature (use bc=bcc is you wish):
bcc = 0.5*log(1.0+sqrt(2.0));
NLs = words(Ls); # The number of lattice sizes
LL(i) = word (Ls,i); # Returns the i_th lattice size
clplot(i) = sprintf("\n<grep 'm%#s' all1|sort -k 3.3g|awk -v L=%#s -v bc=%f -v nu=%f -v gnu=%f \" '{print L^(1.0/nu)*(bc-$3)/bc,.L^(-gnu)*$6,.L^(-gnu)*$7}'",LL(i),LL(i),bc,nu,gnu);"
```
14.10. STUDYING SCALING WITH COLLAPSE

\[
\begin{align*}
\text{set macros} \\
\text{set term wxt enhanced} \\
\text{set title } \text{sprintf("b_c= %f nu= %f g/n= %f", bc, nu, gnu)} \\
\text{set xlabel } "x=L^{1/\nu} t" \\
\text{set ylabel } "F(x) = L^{-(g/n)} \chi(\{/\text{Symbol b}\}.L)" \\
\text{plot for[i=1:NLs] cplot(i) u 1:2:3 w e t sprintf("L=%s",LL(i))}
\end{align*}
\]

In order to use the above program, we give the gnuplot commands

\[
\begin{align*}
\text{gnuplot> } & \text{Ls = "40 60 80 100 120 140 160 200 500 1000"} \\
\text{gnuplot> } & \text{bc = 0.4406868; nu = 1; gnu = 1.75;} \\
\text{gnuplot> } & \text{load "scale_gamma.gpl"}
\end{align*}
\]

The first two lines define the parameters of the plot. The variable Ls contains all the lattice sizes that we want to study, each value of L separated from another by one or more spaces. The variables bc, nu, gnu are the parameters \(\beta_c, \nu\) and \(\gamma/\nu\) that will be used in the scaling relation (14.59). The third command calls the program that makes the plot. If we need to vary the parameters, then we redefine the corresponding variables and repeat.

In order to dissect the above program, look at the online help manual of gnuplot\(^3\). We will concentrate on the construction of the awk filter that computes the points in the plot properly normalized. The value of the function cplot(i) is a string of characters which varies with \(L\) (the index \(i\) corresponds to the \(i\)-th word of the variable Ls). For each \(i\), this string is substituted in the plot command, and it is of the form "< grep ... L(-gnu)*$7>". The values of the parameters are passed using the function sprintf(), which is called each time with a different value of \(i\). The dirty work is done by awk, which calculates each point (columns 6 and 7: $6, $7 are \(\chi\) and its error \(\delta\chi\)). For a given value of \(L\), the grep component of the filter prints the lines of the file all which contain the magnetization. The sort component sorts data in the order of increasing temperature (column 3: -k3,3g)

Can we make the above study more systematic and apply quantitative criteria for the quality of the collapse, which will help us estimate the error in the results? One crude way to estimate errors is to split the data in \(n_b\) bins and work independently on each set of data. Each bin will give

---

\(^3\)In order to look for help from gnuplot’s online help system, use the commands help word, help words, help macros, help sprintf, help plot iteration
an optimal set of parameters \((\beta_c, \nu, \gamma/\nu)\) which will be assumed to be an independent measurement. The errors can be calculated using equation (13.39) (for \(n = n_b\)).

In order to provide a quantitative measure of the quality of the collapse, we define a \(\chi^2/\text{dof}\) similar to the one used in data fitting, as discussed in appendix 13.7. When the distance between the collapsing curves increases, this \(\chi^2/\text{dof}\) should increase. Assume that our measurements consist of \(N_L\) sets of measurements for \(L = L_1, L_2, \ldots, L_{N_L}\). After setting the parameters \(p \equiv (\beta_c, \nu, \gamma/\nu)\) and an interval \(\Delta x \equiv [x_{\text{min}}, x_{\text{max}}]\), we calculate the data sets \(\{(x_{i,k}, F(x_{i,k}; p, L_i))\}_{k=1}^{n_i}\), for all \(x_{i,k} \in \Delta X\), using our measurements. The data sets consist of \(n_i\) points of the data for \(L = L_i\), for which the \(x_k\) are in the interval \(\Delta x\). For each point \(x_{i,k}\), we calculate the scaling function \(F(x_{i,k}; p, L_i) = L_i^{-\gamma/\nu} \chi(\beta_{i,k}, L_i)\), which depends on the chosen parameters \(p\) and the lattice size \(L_i\). Then, we have to choose an interpolation method, which will define the interpolation functions \(F(x_{i,k}; p, L_i)\)\(^{38}\), so that we obtain a good estimate of the scaling function between two data points. Then, each point \(\{(x_{i,k}, F(x_{i,k}; p, L_i))\}_i\) in a data set has a well defined distance from every other data set \(j\) \((j = 1, \ldots, N_L \text{ and } j \neq i)\), which is defined by the distance from the interpolating function of the other sets. This is equal to \(^{39}\) \(|F(x_{i,k}; p, L_i) - F_x(x_{i,k}; p, L_j)|\).

We define the quantity

\[
\chi^2(p; \Delta x) = \frac{1}{N_L(N_L - 1)n_{\text{points}}} \times \sum_{i=1}^{N_L} \sum_{j=1,j\neq i}^{N_L} n_i \sum_{k=1}^{n_i} \frac{(F(x_{i,k}; p, L_i) - F(x_{i,k}; p, L_j))^2}{(\delta F(x_{i,k}; p, L_i))^2},
\]

where \(n_{\text{points}} = \sum_{i=1}^{N_L} n_i\) is the number of terms in the sum. The normalization constant \(N_L(N_L - 1)\) is used, because this is the number of pairs of curves in the sum. Each term is weighted by its error \(\delta F(x_{i,k}; p, L_i)\), so that points with small error have a larger contribution than points with large error. This is the definition used in [71], but you can see other approaches in [4], [69].

The \(\chi^2(p; \Delta x)\) depends on the parameters \(p\) and the interval \(\Delta x\). Initially, we keep \(\Delta x\) fixed and perform a minimization with respect to

---

38 This can be a polynomial interpolation, a cspline interpolation or one of its generalizations or multihistogramming. The last one is slightly more involved but carries smaller systematic errors.

39 You can see the necessity of the interpolation, since the value \(x_{i,k}\) most likely doesn’t exist in the data set \(j\).
the parameters $p$. The minimum is given by the values $p_{\text{min}}$ and these values are the estimators that we are looking for. In order to calculate the errors $\delta p$ we can bin our data according to the discussion on page 623. Alternatively, we may assume a $\chi^2$ distribution of the measurements, and if the minimum $\chi^2 \lesssim 1$, then the intervals of the parameter values that keep $\chi^2 \lesssim 2$ give an estimate of the errors in the parameters.

The results depend on the chosen interval $\Delta x$. Usually [69], this is chosen so that its center is at the maximum of $F(x)$ so that $\Delta x = [x_{\text{max}} - \delta x, x_{\text{max}} + \delta x]$. If $\delta x$ is larger than it should, then $\chi^2(p_{\text{min}}; \Delta x)$ is large and we don’t have good scaling. If it is too small, then the errors $\delta p$ will be large. By taking the limit $\delta x \to 0$, we calculate $p$ by studying the convergence of $p_{\text{min}}$ to stable, optimal with respect to error, values (see figure 8.7, page 238 in [4] as well as [69]).

14.11 Binder Cumulant

Up to now, we have studied fluctuations of observables by computing second order cumulants. The calculation of the critical temperature, the order of the phase transition and the critical exponents can also be done by computing higher order cumulants and sometimes this calculation gives more accurate and clear results. The most famous one is the Binder cumulant which is a fourth order cumulant, and its name derives from Kurt Binder who studied it first [72,73].

\[
U = 1 - \frac{\langle m^4 \rangle}{3 \langle m^2 \rangle}.
\] (14.63)

Appendix 14.12 discusses its properties in detail. For a continuous phase transition

\[
U = \begin{cases} 
0 & \beta \ll \beta_c \ 
U^* & \beta = \beta_c \\
\frac{2}{3} & \beta \gg \beta_c
\end{cases},
\] (14.64)

where for the Ising model on a square lattice $U^* = 0.610690(1)$ [73]. The value $U = 0$ corresponds to the Gaussian distribution, whereas the value $U = 2/3$ corresponds to two Gaussian distributions of small width around two symmetric values $\pm \langle m \rangle$ (see problems 14 and 15).

---

In statistics, the 4th order cumulant of a random variable $x$ is equal to $\kappa_4 = \langle (x - \langle x \rangle)^4 \rangle - 3 \langle (x - \langle x \rangle)^2 \rangle$ and $\kappa_2 = \langle (x - \langle x \rangle)^2 \rangle$, so that $U = -\kappa_4/3\kappa_2$ for $x = m$ and $\langle m \rangle = 0$. 
It practice, it is found that finite size corrections to $U^*$ are small, therefore the calculation of $U(\beta, L)$ gives an accurate measurement of the critical temperature $\beta_c$. The curves $U(\beta, L)$ intersect at the point $(\beta_c, U^*)$ for different $L$ and this point gives a very good estimate of $\beta_c$.

Figure 14.30: Binder cumulant for the Ising model on the square lattice for different temperatures and lattices sizes. The horizontal line is the expected value $U^* = 0.610690(1)$.

Figure 14.30 shows our measurements for $U(\beta, L)$. The intersection of the curves in the figure at a single point $(\beta_c, U^*)$ is impressively accurate. Table 14.6 shows an attempt to calculate $\beta_c$ systematically by computing the critical temperature from the intersection of the curves $U(\beta, L)$ for three values of $L$. By taking into account all the measurements for $L = 100 - 1000$ the computed result is

$$\beta_c = 0.440678(9) \quad U^* = 0.6107(4), \quad (14.65)$$

which is in a very good agreement with the expected values $\beta_c = 0.44068679 \ldots$, $U^* = 0.610690(1)$. Notice that, in the calculation of $U^*$ the systematic error due to finite size effects decreases with increasing $L$, whereas the statistical error increases due to the increase of the slope of the curves $U(\beta, L)$ near the point $\beta = \beta_c$. But the accuracy of the calculation of $\beta_c$ turns out to be better with increasing $L$.

Finite size scaling can also be applied to the Binder cumulant in order to calculate $\beta_c$ and $1/\nu$. From equation (14.90) (14.119) of appendix

Table 14.6: The calculation of $\beta_c$ and $U^*$ from the intersection of the curves $U(\beta, L)$ for fixed $L$ shown in figure 14.30. Each calculation uses three values of $L$. The expected values from the theory and the bibliography \[73\] are $\beta_c = 0.44068679\ldots$ and $U^* = 0.610690(1)$ respectively.

\[14.12\] we expect that $U$ scales as

$$U = F_U(x) = F_U(L^{1/\nu} t).$$  \hfill (14.66)

This is confirmed in figure 14.31. From the value $F_U(x = 0)$, we obtain $U^* = 0.6107(4)$, which is consistent with the result \[14.65\].

The numerical calculation of critical exponents, and especially $1/\nu$, can be hard in the general case. Therefore it is desirable to cross check results using several observables which have known scaling behavior. We discuss some of them below\[^42\]. They involve the correlations of the magnetization with the energy.

The derivative of the Binder cumulant is

$$D_U = \frac{\partial U}{\partial \beta} = \frac{\langle m^4 E \rangle \langle m^2 \rangle + \langle m^4 \rangle (\langle m^2 \rangle \langle E \rangle - 2 \langle m^2 E \rangle)}{3 \langle m^2 \rangle^3}.$$  \hfill (14.67)

Its scaling is given by equation \[14.120\]

$$D_U = L^{1/\nu} F_{D_U}(x) = L^{1/\nu} F_{D_U}(L^{1/\nu} t),$$  \hfill (14.68)

which we plotted in figure 14.32. Notice that $D_U$ defines a pseudocritical region around its maximum. The scaling of the maximum as well as the scaling of its position can be used in order to compute $1/\nu$, as we did in figures 14.23 and 14.25 for the magnetic susceptibility.

\[^42\]These have been particularly successful in the study of the 3d Ising model \[75\].
Figure 14.31: Scaling of the Binder cumulant for $1/\nu = 1$ and by using the exactly known critical temperature $\beta_c$ in $t = (\beta_c - \beta)/\beta_c$. The inset zooms in the critical region. The horizontal line is the expected result $U^* = 0.610690(1)$ [73].

It could also turn out to be useful to study correlation functions of the form

$$D_{\ln m^n} = \frac{\partial \ln \langle m^n \rangle}{\partial \beta} = \langle E \rangle - \frac{\langle E m^n \rangle}{\langle m^n \rangle}, \quad (14.69)$$

whose scaling properties are given by equation (14.126) of appendix 14.12.

$$D_{\ln m^n} = L^{1/\nu} F_{D_{\ln m^n}}(x) = L^{1/\nu} F_{D_{\ln m^n}}(L^{1/\nu} t). \quad (14.70)$$

In particular we are interested in the case $n=1$

$$D_{\ln |m|} = \frac{\partial \ln \langle |m| \rangle}{\partial \beta} = \langle E \rangle - \frac{\langle E |m| \rangle}{\langle |m| \rangle}, \quad (14.71)$$

and $n=2$

$$D_{\ln m^2} = \frac{\partial \ln \langle m^2 \rangle}{\partial \beta} = \langle E \rangle - \frac{\langle E m^2 \rangle}{\langle m^2 \rangle}. \quad (14.72)$$

We also mention the energy cumulant $V$

$$V = 1 - \frac{\langle e^4 \rangle}{3\langle e^2 \rangle^2}. \quad (14.73)$$
Figure 14.32: Scaling of the derivative of the Binder cumulant \( D_U \) (see equation (14.67)) for \( 1/\nu = 1 \) and \( \beta_c \) equal to its known value in \( t = (\beta_c - \beta)/\beta_c \).

In [76], it is shown that for a second order phase transition \( V^* = 2/3 \), whereas for a first order phase transition, we obtain a non trivial value. Therefore, this parameter can be used in order to determine whereas a system undergoes a first order phase transition. This is confirmed in figure 14.35. The minima of the curves \( V(\beta, L) \) converge to the critical temperature according to (14.50).

14.12 Appendix: Scaling

14.12.1 Binder Cumulant

In section 14.11, we studied the scaling properties of the Binder cumulant

\[
U = 1 - \frac{\langle m^4 \rangle}{3\langle m^2 \rangle^2}
\]

numerically. In this appendix, we will use the general scaling properties of a system that undergoes a continuum phase transition near its critical temperature, in order to derive the scaling properties of \( U \) and its derivatives. For more details, the reader is referred to [73], [6].
The values of $U$ are trivial in two cases: When the magnetization follows a Gaussian distribution, which is true in the high temperature, disordered phase, we have that $U = 0$. When we are in the low temperature, ordered phase, we have that $U = 2/3$. The proof is easy and it is left as an exercise (see problems 14 and 15).

According to the discussion in chapter 14, when the critical temperature $\beta_c$ of a continuum phase transition is approached, the system exhibits scaling properties due to the diverging correlation length $\xi$. If we approach $\beta_c$ from the high temperature phase, then we expect that the distribution function of the magnetization per site $s$ (not its absolute value) is approximately of the form

$$P(L, s) = \frac{1}{\sqrt{2\pi\langle s^2 \rangle}} e^{-\frac{s^2}{2\langle s^2 \rangle}} = \left(\frac{\beta L^d}{2\pi \chi}\right)^\frac{1}{2} e^{-s^2 L^d \beta \chi},$$

which is a Gaussian with standard deviation $\sigma^2 = \langle s^2 \rangle = \chi/(\beta L^d)$. We have temporarily assumed that the system is defined on a $d$–dimensional hypercubic lattice of edge $L$.

When the critical temperature is approached, the distribution function
14.12. APPENDIX: SCALING

Figure 14.34: Scaling of $D\ln m^2$ (see equation (14.72)) for $1/\nu = 1$ using the exact value of $\beta_c$ in $t = (\beta_c - \beta)/\beta_c$.

$P(L, s)$ scales according to the relation [73]

$$P(L, s) = L^x p_0 \tilde{P}(a L^y s, L/\xi), \tag{14.76}$$

where $\xi = \xi(t) = \lim_{L \to \infty} \xi(\beta, L)$, $t = (\beta_c - \beta)/\beta_c$, is the correlation length in the thermodynamic limit. As we approach the critical point, $\lim_{t \to 0} \xi(t) = +\infty$, in such a way that $\xi \sim |t|^{-\nu}$. Equation (14.76) is a scaling hypothesis which plays a fundamental role in the study of critical phenomena.

In order to calculate the exponents in equation (14.76), we apply the normalization condition of a probability distribution function

$$1 = \int_{-\infty}^{+\infty} ds P(L, s) = L^x p_0 \int_{-\infty}^{+\infty} ds \tilde{P}(a L^y s, L/\xi) = L^x p_0 \frac{1}{a L^y} \int_{-\infty}^{+\infty} dz \tilde{P}(z, L/\xi) = L^{x-y} p_0 \frac{1}{a} \int_{-\infty}^{+\infty} dz \tilde{P}(z, L/\xi), \tag{14.77}$$

where we set $z = a L^y s$. For the left hand side to be equal to one, we
Figure 14.35: The energy cumulant defined by equation (14.73). As $L$ is increased, its value converges to $2/3$, as expected for a second order phase transition. The position of the minima converge to the critical temperature as $L^{-1/v}$ must have that $x = y$,

$$C_0 \equiv \int_\infty^{+\infty} dz \, \tilde{P}(z, \frac{L}{\xi}) < \infty, \quad (14.78)$$

and $p_0 = a/C_0$. $C_0 = C_0(L/\xi)$, $p_0 = p_0(L/\xi)$ and $p_0C_0 = a$ is a constant independent of $L$ and $\xi$. Finally, we obtain

$$P(L, s) = \frac{a}{C_0} L^y \tilde{P}(aL^y s, \frac{L}{\xi}). \quad (14.79)$$

The moments of the distribution of the spins $\langle s^k \rangle$ are

$$\langle s^k \rangle = \int_\infty^{+\infty} ds \, s^k P(L, s)$$

$$= \frac{a}{C_0} L^y \int_\infty^{+\infty} ds \, s^k \tilde{P}(aL^y s, \frac{L}{\xi})$$

$$= \frac{a}{C_0} L^y \frac{1}{a^{k+1}L^{(k+1)y}} \int_\infty^{+\infty} dz \, z^k \tilde{P}(z, \frac{L}{\xi})$$

$$= L^{-ky} F_k \left( \frac{L}{\xi} \right), \quad (14.80)$$
where the last line is the definition of the function $F_k(x)$. When we first take the thermodynamic limit $L \to \infty$ and then approach the critical temperature $t \to 0$, the correlation length $\xi \to \infty$ diverges in such a way that $L/\xi \to \infty$. In the region $\beta < \beta_c$ ($\langle m \rangle = 0$) we have that $\chi = \beta L^d \langle s^2 \rangle$, and by using the relations

$$\chi = \chi_+ t^{-\gamma}, \quad \xi = \xi_+ t^{-\nu} \quad \Rightarrow \quad \chi = \frac{\chi_+}{\xi_+^{\gamma/\nu}} \xi^{\gamma/\nu} \sim \xi^{\gamma/\nu}, \quad (14.81)$$

we obtain

$$\langle s^2 \rangle = \beta^{-1} L^{-d} \chi = \frac{\chi_+}{\beta L^d \xi_+^{\gamma/\nu}} \xi^{\gamma/\nu} \sim \xi^{\gamma/\nu}. \quad (14.82)$$

In the above equations, we introduced the universal amplitudes $\chi_+$ and $\xi_+$, which are universal constants (i.e. they are the same within a universality class) and they are defined from equation (14.81). In this limit, in order for (14.80) to have consistent scaling for $k = 2$ on the right and left hand sides, we obtain (compare with equation (14.57))

$$F_2 \left( \frac{L}{\xi} \right) \sim \left( \frac{L}{\xi} \right)^{-\gamma/\nu} \quad \text{for} \quad \frac{L}{\xi} \gg 1. \quad (14.83)$$

In order to compute the $L$-scaling, we substitute the above equations to (14.80) for $k = 2$, and we obtain

$$\frac{\chi_+}{\beta L^d \xi_+^{\gamma/\nu}} \xi^{\gamma/\nu} \sim L^{-2y} \left( \frac{L}{\xi} \right)^{-\gamma/\nu}. \quad (14.84)$$

Then, we obtain

$$L^{-d} \sim L^{-2y} L^{-\gamma/\nu} \Rightarrow d = 2y + \frac{\gamma}{\nu} \Rightarrow y = \frac{d\nu - \gamma}{2\nu} = \frac{\beta}{\nu}, \quad (14.85)$$

where we used the known hyperscaling relation

$$d\nu = \gamma + 2\beta. \quad (14.86)$$

Finally, we obtain the equations $\beta < \beta_c$.

$$P(L, s) = \frac{a}{C_0} L^{\beta/\nu} \tilde{P}(aL^{\beta/\nu} s, \frac{L}{\xi}), \quad (14.87)$$

\(^*\)i.e. both sides should scale w.r.t to the correlation length as $\sim \xi^{\gamma/\nu}$.  
\(^\dagger\)See e.g. [74], equations 3.35, 3.36, 3.53.
\[ \langle s^2 \rangle = L^{-2\beta/\nu} F_2 \left( \frac{L}{\xi} \right), \]  
\[ \langle s^4 \rangle = L^{-4\beta/\nu} F_4 \left( \frac{L}{\xi} \right), \]

which are valid in the disordered phase \( \beta < \beta_c \). From equation (14.74), we find that the critical behavior of the Binder cumulant is

\[ U \sim 1 - \frac{L^{-4\beta/\nu} F_4 \left( \frac{L}{\xi} \right)^2}{3 L^{-4\beta/\nu} F_2 \left( \frac{L}{\xi} \right)^2} = 1 - \frac{1}{3} \frac{F_4 \left( \frac{L}{\xi} \right)}{F_2 \left( \frac{L}{\xi} \right)^2}. \]  

(14.90)

Finite size effects dominate in the pseudocritical region, in which case we take the thermodynamic limit \( L \to \infty \) keeping \( L/\xi \) finite, and the fluctuations get suppressed, rendering the functions \( F_k(x) \) finite. Therefore, we obtain\(^5\)

\[ \lim_{L \to \infty} U(t = 0, L) \equiv U^* = 1 - \frac{1}{3} \frac{F_4(0)}{F_2(0)^2} = \text{const.}, \]  

(14.91)

which shows why the value of \( U \) at the critical temperature turned out to be almost independent of the system size \( L \). \( U^* \) is found to depend on the boundary conditions and on the anisotropy of the interaction. For the Ising model on the square lattice we have that \(^7\)\(^3\) (Kamieniarz+Blöte)

\[ U^* = 0.610690(1) \]  

(14.92)

### 14.12.2 Scaling

Consider a change of length scale on a lattice so that

\[ \xi \to \frac{\xi}{b}, \]  

(14.93)

where \( \xi \) is the dimensionless correlation length in the thermodynamic limit and \( b \) is the scaling factor. Then, the basic assumption for the scaling of thermodynamics quantities in the region of a continuous phase transition is that the free energy is changed according to \(^9\)

\[ f(t, h) = b^{-d} f(tb^\mu, hb^\nu), \]  

(14.94)

\(^5\)At \( t = 0 \) we have \( \xi(0) = +\infty \), therefore for finite \( L \) we have that \( L/\xi = 0 \).

\(^7\)More precisely the singular part of the free energy.
where $t$ is the reduced temperature and $h$ is the external magnetic field. The above relation summarizes the scaling hypothesis, and it is a relation similar to (14.76). This relation can be understood through the renormalization group approach, and the fundamental assumption is the appearance of a unique dynamical length scale that diverges as we approach the critical point. The arguments $tb^{ny}$ and $hb^{hy}$ give the change in the coupling constants $t$ and $h$ under the change in length scale in order that the equation remains valid.

By applying the above relation $n$ times we obtain

$$f(t, h) = b^{-nd} f(tb^{ny}, hb^{ny}).$$  \hfill (14.95)

If we take $n \to \infty$, $t \to 0$, keeping the product $tb^{ny} = t_0 = O(1)$ fixed, we obtain

$$f(t, h) = t^{d/ny} f(t_0, ht^{-ny/y_n}) = t^{d/ny} \Psi(ht^{-ny/y_n}) = t^{2-\alpha} \Psi(ht^{-ny/y_n}),$$  \hfill (14.96)

where we substituted $b^n \sim t^{-1/y_n}$ and defined the scaling function $\Psi(z)$ and the critical exponent

$$\alpha = 2 - \frac{d}{y_h}.$$  \hfill (14.97)

By applying the same reasoning to (14.93) for the correlation length we obtain

$$\xi(t, h) = b^{-1} \xi(tb^{ny}, hb^{ny}) = \ldots = b^{-n} \xi(tb^{ny}, hb^{ny}).$$  \hfill (14.98)

By taking the limit $n \to \infty$, $t \to 0$, keeping the product $tb^{ny} = O(1)$, the left hand side will give a finite value, e.g. $\xi_0 < \infty$ whereas the right hand side will give

$$\xi_0 = t^{1/ny} \xi(t_0, ht^{-ny/y_n}).$$  \hfill (14.99)

By considering the case $h = 0$, and by comparing to the known relation (14.4) $\xi \sim t^{-\nu}$, we obtain

$$\xi = \xi_0 t^{-1/ny} \Rightarrow \nu = \frac{1}{y_h}.$$  \hfill (14.100)

By taking the derivative of (14.96) with respect to the temperature, we obtain

$$\frac{\partial f}{\partial t} \sim t^{1-\alpha} \Psi(ht^{-ny/y_n}) + t^{2-\alpha} ht^{-ny/y_n-1} \Psi'(ht^{-ny/y_n}).$$  \hfill (14.101)

\footnote{See e.g. chapter 3 in [74].}
We use the notation $\sim$ whenever we neglect terms that are not related to the scaling properties of a function.

By taking the derivative once more, and by setting $h = 0$, we obtain the specific heat

$$c \sim \frac{\partial^2 f}{\partial t^2} \sim t^{-\alpha} \Psi(0).$$

Therefore, the critical exponent $\alpha$ is nothing but the critical exponent of the specific heat defined in equation (14.4).

The magnetic susceptibility can be obtained in a similar way by taking the derivative of (14.96) with respect to $h$

$$\frac{\partial f}{\partial h} \sim t^{d/\nu} t^{-\gamma_h/\nu} \Psi'(h t^{-\gamma_h/\nu}) \sim t^{\nu d-\nu y_h} \Psi'(h t^{-\nu y_h}).$$

By taking the derivative once more time and by setting $h = 0$ we obtain the magnetic susceptibility

$$\chi \sim \frac{\partial^2 f}{\partial h^2} \sim t^{\nu d-2\nu y_h} \Psi'(0),$$

and, by comparing to (14.3) $\chi \sim t^{-\gamma}$, we obtain

$$\gamma = 2\nu y_h - \nu d \iff y_h = \frac{1}{2}(d + \frac{\gamma}{\nu}) = d - \frac{\beta}{\nu} = \frac{\beta + \gamma}{\nu}$$

In the last two equations we used the hyperscaling relations

$$\nu d = \gamma + 2\beta.$$  

### 14.12.3 Finite Size Scaling

We will now extend the analysis of the previous section to the case of a system of finite size. We will assume that the system’s degrees of freedom are located on a lattice whose linear size is $l = L a$ (the volume is $V = l^d$, $d$ is the number of dimensions), where $L$ is the (dimensionless) number of lattice sites and $a$ is the lattice constant. We consider the limit $L \to \infty$ and $a \to 0$, so that $l$ remains constant. By changing the $L$-scale

$$L \to \frac{L}{b} \iff L^{-1} \to bL^{-1},$$

and

$$a \to ba,$$
equation (14.94) generalizes to
\[ f(t, h, L^{-1}) = b^{-nd} f(tb^{ny}, hL^{ny}, b^n L^{-1}). \] (14.109)

By taking the limit \( t \to 0, \ n \to \infty \) and \( tb^{ny} = t_0 < \infty \Rightarrow b^n \sim t^{-1/ny} \) (approach of the critical point), the above relation becomes
\[ f(t, h, L^{-1}) = t^{d/ny} f(t_0, ht^{-yn/y}, t^{-1/ny} L^{-1}) = t^{d/ny} \Psi(ht^{-yn/y}, t^{-1/ny} L^{-1}). \] (14.110)

By differentiating and setting \( h = 0 \) as in the previous section we obtain
\[ \chi(t, L^{-1}) = \frac{\partial^2 f}{\partial h^2}\bigg|_{h=0} = t^{-\gamma} \phi_2(L^{-1}t^{-\nu}) = t^{-\gamma} \phi_2\left(\frac{\xi}{L}\right), \] (14.111)

where we set \( y_t = 1/\nu, \phi_2(x) = \Psi^{(2,0)}(0, x) = \partial^2 \Psi(z, x)/\partial z^2\big|_{z=0}. \)

The thermodynamic limit is obtained for \( L \gg \xi \) where \( \phi_2\left(\frac{\xi}{L}\right) \to \phi_2(0) < \infty \), which yields the known relation \( \chi \sim t^{-\gamma} \).

When \( L \) is comparable to \( \xi \), finite size effects dominate. The large fluctuations are suppressed and the magnetic susceptibility has a maximum at a crossover (pseudocritical) temperature \( t_X \equiv (\beta_c - \beta_c(L))/\beta_c \), where \( t_X \sim L^{-1/\nu} \). The last relation holds because \( L \sim \xi \sim t^{-\nu} \) by assumption. We obtain
\[ \chi_{\text{max}} \sim t_X^{-\gamma} \phi_2(L^{-1}t_X^{-\nu}) \sim L^{\gamma/\nu} \phi_2(L^{-1}L) \sim L^{\gamma/\nu} \phi_2(1) \sim L^{\gamma/\nu}. \] (14.112)

In the region of the maximum, we obtain the functional form
\[ \chi(t, L^{-1}) = L^{\gamma/\nu} F_\chi(L^{1/\nu} t), \] (14.113)

which is nothing but equation (14.59). The function \( F_\chi(x) \) is analytic in its argument \( x = L^{1/\nu} t \), since for a finite system \( \chi(t, L^{-1}) \) is an analytic function of the temperature.\(^{48}\) In the thermodynamic limit (\( L \to \infty \) and \( |t| > 0 \), therefore \( x \to \infty \))
\[ F_\chi(x) \sim x^{-\gamma} \quad x \gg 1, \] (14.114)

so that \( \chi(t, L^{-1}) = L^{\gamma/\nu} F_\chi(L^{1/\nu} t) \sim L^{\gamma/\nu} (L^{1/\nu} t)^{\gamma} \sim t^{-\gamma} \). Near the pseudocritical point
\[ F_\chi(x) = F_{\chi,0} + F_{\chi,1} x + F_{\chi,2} x^2 + \ldots \quad x \ll 1, \] (14.115)

\(^{48}\)We stress again that \( \xi \sim t^{-\nu} \) in (14.111) is the correlation length in the thermodynamic limit and not at finite \( L \).

\(^{49}\)This is because the partition function is an analytic function of the temperature. Therefore it is \( x = L^{1/\nu} t \) which is the scaling variable and not a power of it, such as \( \bar{x} \) used in (14.53) and (14.54).
and we expect that for $L^{1/\nu t} \ll 1$ we have that

$$\chi(t, L^{-1}) = L^{\gamma/\nu} \left(1 + \chi_1 L^{1/\nu t} + \chi_2 L^{2/\nu t^2} + \ldots\right). \quad (14.116)$$

The above relations lead to the following conclusions:

- The pseudocritical point shifts as $\sim L^{-1/\nu}$ (equation (14.50))

- The peak of the magnetic susceptibility increases as $\chi_{\text{max}} \sim L^{\gamma/\nu}$

- The direction of the shifting of the maximum of the magnetic susceptibility depends on the boundary conditions:
  - Periodic boundary conditions suppress the effects of the fluctuations, since the wave vectors are limited by $2\pi L^{-1}$. This increases the pseudocritical temperature $T_c(L)$ ($\beta_c(L) < \beta_c \Rightarrow c > 0$ in (14.50)).
  - Free boundary conditions lead to free fluctuations on the boundary, which decrease the pseudocritical temperature $T_c(L)$ ($\beta_c(L) > \beta_c \Rightarrow c < 0$ in (14.50)).
  - Frozen (fixed) spins on the boundary lead to increased order in the system. This increases the pseudocritical temperature $T_c(L)$ ($\beta_c(L) < \beta_c \Rightarrow c > 0$ in (14.50)).

We conclude that $F_k(L^{1/\nu t})$ depends on the boundary conditions and the geometry of the lattice.

Similarly, we obtain

$$\langle m^k \rangle \sim L^{-d} \frac{\partial^k f}{\partial h^k} \sim L^{-d} t^d/y_{k/n} y_{n/y} \phi_k \left(L^{-1} t^{-\nu}\right) \sim L^{-d} t^{d-k/n} \phi_k \left(\frac{\xi}{L}\right), \quad (14.117)$$

and by following similar arguments leading to (14.113), we obtain

$$\langle m^k \rangle \sim L^{-d} L^{-d+k/n} F_k(L^{1/\nu t}) \sim L^{k-\frac{n}{d}} F_k(L^{1/\nu t}). \quad (14.118)$$

For the Binder cumulant we obtain

$$U = 1 - \frac{\langle m^4 \rangle}{3\langle m^2 \rangle^2} \sim 1 - \frac{L^{4y_n} F_4(L^{1/\nu t})}{3(L^{2y_n} F_2(L^{1/\nu t}))^2} \sim U_s + U_1 (L^{1/\nu t}) + U_2 (L^{1/\nu t})^2 + \ldots, \quad (14.119)$$

where in the last equality we expanded the analytic functions $F_{2,4}(L^{1/\nu t})$ for small $L^{1/\nu t}$. Then, we see that

$$\frac{\partial U}{\partial \beta} \sim \partial_1 U \sim L^{1/\nu}. \quad (14.120)$$
By differentiating (14.110) with respect to the temperature we obtain

$$\frac{\partial f}{\partial t} \sim t^{d/y} \Psi \left(h t^{y/y}, L^{-1} t^{-1/y} \right)$$

$$+ t^{d/y} \left(h t^{y/y} - 1 \right) \Psi^{(1,0)} \left(h t^{y/y}, L^{-1} t^{-1/y} \right)$$

$$+ t^{d/y} L^{-1} t^{-1/y} - 1 \Psi^{(0,1)} \left(h t^{y/y}, L^{-1} t^{-1/y} \right)$$

$$\sim t^{d-1} \Psi \left(h t^{y/y}, L^{-1} t^{-\nu} \right)$$

$$+ t^{d+\nu y} \Psi^{(1,0)} \left(h t^{y/y}, L^{-1} t^{-\nu} \right)$$

$$+ L^{-1} t^{d-1-\nu} \Psi^{(0,1)} \left(h t^{y/y}, L^{-1} t^{-\nu} \right), \quad (14.121)$$

where we used the notation $\Psi^{(n,m)}(x, z) = \partial^{n+m} \Psi(x, z) / \partial x^n \partial z^m$. The term proportional to $h$ vanishes when we set $h = 0$. In the pseudocritical region, where $t_X \sim L^{-1/\nu}$, the first and third term are of the same order in $L$ and we obtain

$$\left. \frac{\partial f}{\partial t} \right|_{h=0} = \left. L^{-d+\frac{1}{\nu}} F^1 \left( L^{1/\nu} t \right) \right|_{h=0} = (14.122)$$

and by successive differentiation

$$\left. \frac{\partial^k f}{\partial t^k} \right|_{h=0} = \left. L^{-d+\frac{k}{\nu}} F^k \left( L^{1/\nu} t \right) \right|_{h=0}, \quad (14.123)$$

The derivatives

$$\left. \frac{\partial^2 f}{\partial t \partial h} \right|_{h=0} = \left. L^{-d+yh+\frac{1}{\nu}} F^1 \left( L^{1/\nu} t \right) \right|_{h=0} = \left. \frac{L^{1-\beta}}{L^{-d+\nu y}} \right|_{h=0}, \quad (14.124)$$

$$\left. \frac{\partial^{1+k} f}{\partial t \partial h^k} \right|_{h=0} = \left. L^{-d+kyh+\frac{1}{\nu}} F^k \left( L^{1/\nu} t \right) \right|_{h=0}. \quad (14.125)$$

In particular

$$\frac{\langle E m^k \rangle}{\langle m^k \rangle} = \left. \frac{\partial^{1+k} f}{\partial t \partial h^k} \right|_{h=0} \sim \frac{L^{-d+kyh+\frac{1}{\nu}}}{L^{-d+\nu y}} \sim L^{1/\nu} \quad (14.126)$$

$$\frac{\langle e^4 \rangle}{\langle e^2 \rangle^2} = \left. \frac{L^{-d} \frac{\partial^2 f}{\partial t^2}}{\left( L^{-d} \left. \frac{\partial^2 f}{\partial t^2} \right|_{h=0} \right)^2} \right|_{h=0} \sim \frac{L^{-\frac{\beta}{2}}}{(L^{-\frac{\beta}{2}})^2} \sim \text{const.} \quad (14.127)$$
14.13 Appendix: Critical Exponents

14.13.1 Definitions

\[ \alpha : \ c \sim t^{-\alpha}, \quad c_{\text{max}} \sim L^{\alpha/\nu}, \quad c(t, L) = L^{\alpha/\nu} F^{2}(L^{1/\nu} t) \]

\[ \beta : \ m \sim t^{\beta}, \quad m \sim L^{-\beta/\nu}, \quad m(t, L) = L^{-\beta/\nu} F^{1}(L^{1/\nu} t) \]

\[ \gamma : \ \chi \sim t^{\gamma}, \quad \chi_{\text{max}} \sim L^{\gamma/\nu}, \quad \chi(t, L) = L^{\gamma/\nu} F^{2}(L^{1/\nu} t) \]

\[ \nu : \ \xi \sim t^{-\nu}, \quad \xi \sim L, \]

\[ \delta : \ M \sim h^{1/\delta} \]

\[ z : \ \tau \sim \xi^{z} \]

The scaling relation

\[ f(t, h) = t^{d/\nu} \Psi(h t^{y_{h}/\nu}) \] (14.129)

defines the exponents \( y_{t}, y_{h} \). The relation

\[ G(r, t = 0) \sim \frac{1}{r^{d - 2 + \eta}}, \] (14.130)

defines the exponent \( \eta \) coming from the two point correlation function \( G(r, t) = \langle s(r) \cdot s(0) \rangle \).

14.13.2 Hyperscaling Relations

From the definitions and the hyperscaling relations we have that

\[ \alpha + 2\beta + \gamma = 2 \]
\[ \gamma + 2\beta = \nu d \]
\[ 2 - \nu d = \alpha \]
\[ \alpha + \beta(1 + \delta) = 2 \]
\[ \nu(2 - \eta) = \gamma \] (14.131)

\[ y_{t} = \frac{1}{\nu} = \frac{d}{2 - \alpha}, \quad y_{h} = \frac{\beta + \gamma}{\nu} = \frac{1}{2} \left( d + \frac{\gamma}{\nu} \right) = d - \frac{\beta}{\nu} \] (14.132)

\[ \alpha = 2 - \frac{d}{y_{h}} \quad \beta = \frac{d - y_{h}}{y_{h}} \quad \gamma = \frac{2y_{h} - d}{y_{t}} \quad \delta = \frac{y_{h}}{d - y_{h}} \] (14.133)

\[ \eta = d + 2 - 2y_{h} \Leftrightarrow d - 2 + \eta = 2(d - y_{h}) \] (14.134)

The files all and allem in the accompanying software contain measurements that you can use for your data analysis or compare them with your own measurements.

1. Compute the average acceptance ratio \( \bar{A} \) for the Metropolis algorithm as a function of the temperature for \( L = 10, 40, 100 \). Compute the average size \( \langle n \rangle \) of the Wolff clusters at the same values of the temperatures. Then calculate the number of Wolff clusters that are equivalent to a Metropolis sweep. Make the plots of all of your results and connect the points corresponding to the same \( L \).

2. Make the plots in figures 14.6–14.10 and add data for \( L = 50, 120, 140, 160, 180, 200 \).

3. Make the plots in figures 14.11–14.12 and add data for \( L = 50, 90, 130, 150, 190, 250 \). Recalculate the dynamic exponent \( z \) using your data.

Table 14.7: Critical exponents of the models referred to in the first column. Whenever the value is shown as a floating point number, the exponents are approximate. For the approximate values we don’t apply the hyperscaling relations, but we simply mention the values reported in the bibliography. The values for the 3d Ising model in [77] are a conjecture. For the 3d Ising see also [43] p. 244. 3d XY and 3d AF \( q=3 \) Potts are conjectured to belong to the same universality class.
4. Make the plot in figure 14.13 and add data for $L = 30, 50, 70, 90$. Recalculate the dynamic exponent $z$ using your data.

5. Reproduce the results shown in table 14.1. Add a 6th column computing $\tau_m^{A}_{\text{Metropolis}} = \tau_m \text{Metropolis} / \bar{A}$, where $\bar{A}$ is the average acceptance ratio of the Metropolis algorithm. This changes the unit of time to $N$ accepted spin flips. These are the numbers that are directly comparable with $\tau_m$.

6. Simulate the 2d Ising model on the square lattice for $L = 10, 20, 40, 80, 100$. Choose appropriate values of $\beta$, so that you will be able to determine the magnetic susceptibility and the specific heat with an accuracy comparable to the one shown in table 14.5. In each case, check for the thermalization of the system and calculate the errors.

7. Make the fits that lead to the results (14.38), (14.39), (14.41) and (14.43).

8. Study the scaling of the specific heat as a function of the temperature. Compare the quality of the fits to the functions $a \log|t|$ and $a |t|^\alpha$ by computing the $\chi^2$/dof according to the discussion in appendix 13.7 after page 548.

9. Consider the table 14.8 showing the measurements of $\chi(\beta_c, L)$, $\langle m \rangle(\beta_c, L)$ and $c(\beta_c, L)$. Use the values in this table in order to make the fits which give the exponents $\gamma/\nu$, $\beta/\nu$ and $\alpha$ as described in the text. For the exponent $\alpha$, try fitting to a power and a logarithm and compare the results according to the discussion in the text.

10. Consider the table 14.5 which gives the results of the measurements of $L$, $\beta_c(L)$, $\chi_{\text{max}}$, $\beta'_c(L)$ and $c_{\text{max}}$. Make the appropriate fits in order to calculate the exponents $1/\nu$, $\gamma/\nu$, $\alpha/\nu$ and the critical temperature $\beta_c$ as described in the text. For the exponent $\alpha$, try fitting to a power and a logarithm and compare the results according to the discussion in the text.

11. Reproduce the collapse of the curves shown in figures 14.27-14.29. Use the data in the file all from the accompanying software. Set the appropriate values to the parameters and calculate the scaling functions $F_{x,m,c}$. Vary each parameter separately, so that the collapse becomes not satisfactory and use its variation as an estimate of its error. Determine the range in $x = L^{1/\nu} t$ that gives satisfactory collapse of the curves. Repeat your calculation by performing measurements
Table 14.8: \( \chi(\beta_c, L) \), \( \langle m \rangle(\beta_c, L) \), and \( c(\beta_c, L) \) at the critical temperature for different \( L \) used in problem 9.

12. Prove that for every observable \( O \) we have that \( \frac{\partial \langle O \rangle}{\partial \beta} = -\langle EO \rangle + \langle O \rangle \langle E \rangle = -\langle (E - \langle E \rangle)(O - \langle O \rangle) \rangle \). Using this relation calculate the derivative of the Binder cumulant \( D_U \) and prove equation \( 14.67 \).

13. Use the maximum of the derivative of the Binder cumulant \( D_U \) in order to calculate the critical exponent \( 1/\nu \) according to the analysis shown in figures \( 14.23 \) and \( 14.25 \) for the magnetic susceptibility.

14. Show that for a Gaussian distribution \( f(x) = a e^{-x^2/2\sigma^2} \) we have that \( \langle x^2 \rangle = \sigma^2 \) and \( \langle x^4 \rangle = 3\sigma^4 \). Conclude that \( 1 - \langle x^2 \rangle / (3\langle x^4 \rangle) = 0 \).

15. Consider the distribution given by the probability density distribution

\[
    f(x) = a \left( e^{-\frac{(x-m)^2}{2\sigma^2}} + e^{-\frac{(x+m)^2}{2\sigma^2}} \right).
\]

Plot this function and comment on the fact that it looks, qualitatively, like the distribution of the magnetization in the low temperature phase \( \beta \gg \beta_c \). Show that \( \langle x^4 \rangle = m^4 + 6m^2\sigma^2 + 3\sigma^4 \) and \( \langle x^2 \rangle = m^2 + \sigma^2 \). Interpret your results, i.e. the meaning of each expectation value. Show that for \( \sigma \ll m \) we obtain \( U \approx 2/3 \). Convince yourself that the approximation used concerns the system in the low temperature phase.
16. Calculate the derivative $\partial U/\partial \beta$ as a function of $\langle em^4 \rangle$, $\langle em^2 \rangle$, $\langle m^4 \rangle$ and $\langle m^2 \rangle$. Apply finite size scaling arguments and prove equation (14.120).

17. Use equations (14.131) and $y_t = 1/\nu$, $\gamma = (2y_t - d)/y_t$ in order to prove the other relations in (14.132) and (14.133).

This book is an introduction to the computational methods used in physics, but also in other scientific fields. It is addressed to an audience that has already been exposed to the introductory level of college physics, usually taught during the first two years of an undergraduate program in science and engineering. It assumes no prior knowledge of numerical analysis, programming or computers and teaches whatever is necessary for the solution of the problems addressed in the text.

The book starts with very simple problems in particle motion and ends with an in-depth discussion of advanced techniques used in Monte Carlo simulations in statistical mechanics. The level of instruction rises slowly, while discussing problems like the diffusion equation, electrostatics on the plane, quantum mechanics and random walks. All the material can be taught in two semesters, but a selection of topics can form the material of a one semester course. The book aims to provide the students with the background and the experience needed in order to advance to high performance computing projects in science and engineering. It puts emphasis on hands–on programming of numerical code but also on the production, analysis and interpretation of data. But it also tries to keep the students motivated by considering interesting applications in physics, like chaos, quantum mechanics, special relativity and the physics of phase transitions.

The book and the accompanying software are given under a Creative Commons License/GNU public License as a service to the community. It can be used freely as a whole, or any part of it, in any form, by anyone. There is no official distribution of hard copies, but you can use the printing service of your preference in order produce any number of copies you need for you and/or your students. The ebook can be read in most electronic devices like your PC, tablet or favorite ebook reader and it is freely available from the book’s website.

Konstantinos Anagnostopoulos was educated at the University of Athens and at Syracuse University where he obtained his Ph.D. in theoretical physics in 1993. He has been a researcher at the Institute for Fundamental Theory at the University of Florida, Gainesville and at the Niels Bohr Institute at the University of Copenhagen from 1993 to 1999. He held a visiting professor position at the University of Crete from 1999-2004, and in 2004 he moved to Athens where he has been a member of the faculty of the Physics Department of the National Technical University of Athens (NTUA) ever since. His area of expertise is computational physics with an emphasis in theoretical high energy physics, string theory and quantum gravity. He is a world expert in Monte Carlo simulations of such systems, and he has participated in projects run onto the world’s largest supercomputers. At NTUA he founded three undergraduate computational physics and scientific computing courses at the senior and sophomore level, which he has been teaching since 2004. The audience of those courses are students interested in theoretical physics, but also students majoring in a wider area of applied mathematics, physics and engineering.
